The National Center for Health Statistics—the US Government's principal vital and health statistics agency for over 25 years—works closely with all other federal agencies as well as researchers and academic institutions. The NCHS mission involves such functions as: data collection and analysis, data dissemination, research in statistical and survey methodology, technical assistance in the US and foreign countries, cooperative programs with state, national and international organizations.

NCHS has more than a dozen data systems for collecting information. Data are collected through vital records, personal interviews, physical examinations and laboratory tests, and from hospital, nursing home, and physician records. These data systems are designed to provide information useful to a variety of policymakers in the Congress and the Administration, to medical/health researchers, and others in the health community.

The Center has a new 20-page booklet (DHHS Pub. No. PHS 88-1200), entitled *National Center for Health Statistics: Organization and Activities* which provides an organization chart as well as important background information on the NCHS, including:

- Major Surveys and Data Systems
- Research and Analysis
- Special Activities
- Current Initiatives
- How Do I Work with NCHS?
- How to Access NCHS Data

To obtain a copy of the booklet, contact the Public Affairs Office, National Center for Health Statistics, 3700 East-West Highway, Room 1-20, Hyattsville, MD 20782. Tel: (301) 436-7135.

Improving the Homogeneity of Diagnosis-Related Groups (DRGs) by Using Clinical Laboratory, Demographic, and Discharge Data

ERIC S. GOLDMAN, MD, M. JANET EASTERLING, BA, BSc, AND LEWIS B. SHEINER, MD

Abstract: For 48 of the most common diagnosis-related groups (DRGs) at our hospital, we examined the ability of clinical laboratory tests, demographic data, and ICD-9-CM codes, which provide a measure of severity of illness, to predict patients' length of stay (LOS) more accurately than DRGs alone. For 10 of 20 medical DRGs and 13 of 23 surgical DRGs examined, we were able to increase the ability to predict LOS by at least 10 per cent. The laboratory tests that proved most predictive of LOS over all DRGs were the mean serum sodium, potassium, bicarbonate, and albumin. The system is data driven, objective, and flexible, thus ensuring its utility for the purpose of equitable reimbursement. (*Am J Public Health* 1989; 79: 441–444.)

Introduction

Diagnosis-related groups (DRGs) are currently used to determine reimbursement for Medicare inpatients under the recently instituted prospective payment system (PPS). DRGs, however, may not accurately reflect an individual patient's requirements for hospital resources, due, in part, to the absence of a severity-of-illness measure.[1]

In many institutions, computerized clinical laboratory systems allow access to a patient's test values in machine-readable form. In this study, we provide preliminary evidence that patient data from these sources can improve the ability of DRGs to predict a patient's hospital resource utilization, as proxied by length of stay (LOS). The modified DRGs are produced by an automated, objective, and data driven procedure, eliminating the need for potentially biased or laborious chart review.

Methods

The source of patient data for this study is the Combined Patient Experience (COPE) database, created by merging patient data from computerized sources at the University of California, San Francisco (UCSF) Medical Center.[2] The data include clinical laboratory test results, hospital admission and demographic data, and International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) diagnosis and procedure codes from discharge abstracts. COPE data tapes from the first nine months of 1981 and 1982 were used, including 15,910 and 15,930 admissions, respectively. (The first nine months of data were used because data from the fourth quarter of 1982 were not readily available as a merged data set.) All patients were classified into one of 470 DRGs using the Health Systems International DRG Grouper, running on a Digital Equipment Corporation MicroVAX II supermicrocomputer.

Selection of a DRG for analysis was based on the frequency of admission to the hospital of patients in that DRG, with the goal of examining the top 10 per cent of DRGs. Forty-eight DRGs were chosen, 28 surgical and 20 medical, encompassing 12.7 per cent of all medical-DRG patients (2,027 patient) and 16.7 per cent of all surgical-DRG patients (2,650 patients) for the 1981 time period; figures for 1982 were comparable. Neonatal and obstetric/gynecologic DRGs were excluded from analysis because of a paucity of clinical laboratory test results for patients with those DRGs. Patients whose LOS made them outliers, as defined by Medicare for the DRG to which they were assigned, were excluded from analysis.

The patient attributes selected as candidates for modifying DRGs were age, sex, laboratory test results, ICD-9-CM discharge and diagnosis codes, and status (alive or dead) at discharge. The laboratory tests used were components of the complete blood count (hemoglobin, white blood count); and commonly ordered serum chemistries (sodium, potassium, chloride, total carbon dioxide, blood urea nitrogen, creatinine, albumin, glucose, total protein, calcium, cholesterol, uric acid, total bilirubin, alkaline phosphatase, lactic dehydrogenase, glutamic oxaloacetic transaminase, and phosphorus).

The measures of resource utilization available in the COPE database were LOS and total charges; these were found to be highly correlated with one another ($r = 0.9$), and LOS was chosen as the outcome variable.

All test results were log-transformed (to decrease skewness) and were then centered to the log of the midnormal value for that test and scaled to unit variance. Results were then trimmed at the 5th and 95th percentile values (to delete outliers) by replacing values above or below those percentiles with the values precisely at those percentiles. For each patient admission, the time-weighted mean value for each (transformed) laboratory test was computed by taking the area under the curve of the laboratory test value against time of hospital stay (using the trapezoidal rule), divided by the LOS. In so doing, the test-versus-time curve was extended horizontally from the first (or last) test value to the time of admission (or discharge), if test values on those days were unavailable. When a selected test was not present in a case record, the result was assigned the mid-normal value of that laboratory test.

In addition to the laboratory test variables, the presence or absence in the patient's discharge abstract of each one of a set of ICD-9-CM codes was noted as a separate indicator variable. The set of ICD-9-CM codes for which indicators were defined for a given DRG was chosen as those present for at least 5 per cent of all patients in that DRG in the 1982 (index) data set; four- and five-digit ICD-9-CM codes were truncated to the first three digits. A patient's age, sex, and occurrence of death in hospital were also used as independent variables.

Clearly, the intercorrelations among laboratory tests and

This paper, submitted to the Journal April 6, 1987, was revised and accepted for publication June 22, 1988.

© 1989 American Journal of Public Health 0090-0036/8951.50

their transformations, as well as the large number of independent variables, could give rise to problems of multicollinearity, overfitting, and large computational demand. We chose the linear regression technique, partial least squares (PLS) regression, a latent variables procedure, because it is not much affected by any of these problems.[3]

For each DRG, PLS regression was used to define a (linear) predictor of LOS based on the data described above, using the 1982 data as the index set. To independently validate the LOS predictors thus derived, it was then applied to the 1981 data, which served as the validation set. The R^2 statistic was used as a measure of prediction performance. An R^2 of 0.00 was assigned to all DRGs which did not validate.

After the results using all 19 laboratory tests and all ICD-9-CM codes were obtained for the original data, several representative DRGs were examined to see if the number of laboratory tests in the regression could be reduced. Serum sodium, potassium, total carbon dioxide, and albumin appeared to contribute most of the information to the regressions examined. PLS was therefore re-run for all 48 DRGs in the index set and validated with the 1981 data set as above, using only those four laboratory tests, plus the demographic and ICD-9-CM data. Transformation, trimming, scaling and time-weighted mean were as before.

Results

The results of using the PLS regression defined on the clinical laboratory, demographic, and discharge data of the 1982 index set of patients to predict the LOS within each DRG for the 1981 validation set are summarized in Table 1. In the validation set, for 25 per cent of medical DRGs and 43 per cent of surgical DRGs, we were able to explain at least 10 per cent of the variability in length of stay by using additional clinical data. Overall, in 17 of 48 validation set DRGs examined, the ability of DRGs to predict length of stay was enhanced.

Table 2 summarizes the results when the four most "contributory" laboratory tests mentioned in the Methods section (sodium, potassium, bicarbonate, and albumin) were used selectively. In 23 of 48 validation set DRGs, the ability of DRGs to predict length of stay was improved by at least 10 per cent (50 per cent of medical DRGs and 46 per cent of surgical DRGs). These results were superior to those shown in Table 1, in which all 19 tests were used unselectively (see Discussion below).

Representative PLS regression coefficients created with the index set and used to predict LOS with the validation set for DRG 203, "malignancy of hepatobiliary system or pancreas," are shown in Table 3. Note, in particular, that higher sodium and albumin predict shorter LOS, while increasing age and surgical and radiological procedures predict longer LOS.

Discussion

The DRG system was created by a statistical partitioning process which created multiple new subgroups from "major diagnosis categories" if the reduction in length-of-stay variance (R^2) in the new groups was at least 2.5 per cent.[4] No severity-of-illness measure was used in the creation of these groups. As a result, it is not surprising that we, and other groups,[1,5,6] have shown that DRGs are heterogeneous with respect to hospital resource use.

Two widely discussed systems incorporating severity of illness into DRGs are Disease Staging [1] and the Severity of Illness Index.[5] The Disease Staging system initially required chart review to classify individual patients into stages. A computerized method based on ICD-9-CM codes was eventually developed, but the results of this system did not correlate well with the manual method.[7,8] Further, in one study,[1] the designers of the automated version of Disease Staging were able to explain a maximum of only 16 per cent of variance in total cost within "adjacent" DRGs (aggregated DRGs which ignore age, complications, and comorbidity) using their method.

Horn and colleagues report that their Severity of Illness Index allows major improvements in LOS prediction within DRGs.[9] Further, the system has been shown to be reproducible across institutions.[10] However, the Severity of Illness Index requires chart review for each patient by trained personnel and incorporates subjective ratings of illness severity. Because of its subjectivity, the system has been criticized as being "unusable" for prospective payment.[11] Additionally, the system is potentially "tautological", i.e., the rater could assume that a patient's length of stay is itself an indicator of that patient's severity of illness.[7] A computerized version of the Severity of Illness Index, i.e., Computerized Severity Index (CSI), has been developed[12] in response to these criticisms. This system, like our own, may potentially obviate the subjectivity criticisms. As with the computerized version of the Disease Staging system, however, Horn's CSI requires its own validation studies to document its equivalence to the manual method.

Our system is objective and data driven. The use of time-weighted mean laboratory results protects the system from unscrupulous manipulation; only the duration (relative to LOS) and degree of abnormality, not the frequency of testing nor LOS itself, enters into the predictions. Further, the data driven aspect of the system makes it adaptable both to changes over time and to differences among institutions, since the system itself derives the appropriate regression equations from the data.

TABLE 3—Regression Coefficients of Representative Explanatory Variables Used for Predicting LOS in DRG 203: Malignancy of hepatobiliary system or pancreas

Variables	Data Type	Coefficient	Sign	Explanation
Age	Demogr	0.18	+	Age of patient
NaMean	Clin Lab	0.29	−	Time-weighted-mean sodium
AlbMean	Clin Lab	0.25	−	Time-weighted-mean albumin
155	ICD-9 Dx	0.11	+	Mal. neopl. liver & intrahep. bile ducts
157	ICD-9 Dx	0.10	+	Mal. neopl. pancreas
529	ICD-9 Proc	0.14	+	Other operations on pancreas
922	ICD-9 Proc	0.20	+	Therapeutic radiol. and nuclear medicine

In performing our analyses, we chose to eliminate all patients who were LOS outliers, as defined by the criteria established by the Health Care Financing Administration (HCFA). Such patients are reimbursed differently under Medicare and have essentially been earmarked by HCFA as "distinct" within a DRG. By excluding LOS outliers, we have most likely penalized ourselves, since the LOS of non-outliers within a DRG would be more homogeneous than if they had been included, and, hence, there would be less variance to explain. Nonetheless, by deleting outliers, we have more stringently tested the ability of our system to improve the homogeneity of DRGs.

Logarithmic transformation of the laboratory test results tends to make the results more symmetric in distribution; data trimming moves extreme values towards the mean, eliminating the influence of "unusual" data elements. Although such techniques may be expected to help the predictor derived from fitting an index set be more robust, and hence perform well on an independent, future data set, the R^2 values derived directly from such a data set (here, the validation set) are the ultimate evidence of the validity of a predictor.

The four serum chemistries (sodium, potassium, total carbon dioxide, and albumin) found by our system to be the most important contributors to the regression model have precedent. The APACHE II system[13] found the serum sodium, potassium, and serum pH or bicarbonate at the time of admission to be predictive of resource use in intensive care patients. A study of nutrition-related variables in a group of surgical patients[14] showed that a low serum albumin was the most specific variable related to a length of stay greater than 10 days. Similarly, Baker and colleagues[15] found a high degree of correlation between serum albumin and clinical assessment of preoperative nutritional status in general surgical patients.

While it might seem contradictory that our results were better with only these four tests than with all 19 tests, it must be remembered that the results in question were from a separate validation set. There is nothing in the PLS procedure that guarantees that the final predictor chosen by it is, in fact, optimal among all possible predictors. Apparently, PLS exploited certain associations in the index set when defining its predictor for the 19-test case that simply failed to validate as well as expected.

We have used time-weighted average test results over a patient's entire hospital stay, rather than only admission laboratory results (as in APACHE II), because these values encompass a patient's overall metabolic derangements during his or her hospital stay. One criticism of incorporating tests beyond admission results is that this will not account for iatrogenically induced worsening of a patient's severity of illness. While such worsening would be expected to contribute to LOS, it might not be desirable to "reward" iatrogenic illness by additional compensation in a prospective payment plan. For this reason, we have begun to examine the use of time-weighted mean test results over shorter periods of time, such as the first 48 hours after admission.

A potential weakness of our system is that it depends in part on discharge abstract data, which are subject to coding errors[16] that were particularly problematic in the pre-DRG era. Since the advent of DRGs, however, with an expected decline in erroneous ICD-9-CM assignments,[16] this difficulty has lessened, and we are presently developing a more current data base to test our system further. In any event, by adding "noise," miscoding would decrease, not increase, the apparent value of discharge abstract data in predicting LOS. Another concern regarding the use of ICD-9-CM data is that the procedure codes may inappropriately enhance the predictive power of our system, if in fact they correlate with LOS as indicators of the process of care rather than as measures of severity of illness. We find, however, that more than 75 per cent of the explanatory power of our system comes from clinical laboratory data alone.

Another shortcoming of our methodology is that our results have been validated only with patient data at our hospital. A cross-hospital validation study would be desirable, and such a study is in progress.

EPA Issues Interim Report on Pesticides in Groundwater

The US Environmental Protection Agency recently released an interim report, *Pesticides in Groundwater Data Base*, which summarizes available data on detections of pesticides in groundwater. Not to be confused with the National Pesticide Survey of Drinking Water Wells, the recently released report compiles data from approximately 150 groundwater monitoring studies carried out over the past 10 years by pesticide registrants, universities, and government agencies throughout the country. Findings of the interim report include:

- normal agricultural use has apparently led to residues of 46 different pesticides in the groundwater of 26 states;
- a total of 74 pesticides have been detected in the groundwater of 38 states from all sources, including normal agricultural use, accidental spills, residues from mixing, loading, and disposal of pesticides, back siphoning into wells during irrigation operations, etc;
- most of the pesticide concentrations detected in groundwater were at low levels, with median levels generally below EPA's health advisory levels for these pesticides.

While the interim report points to the potentially wide-ranging presence of pesticides at low levels in groundwater, the results do not offer a comprehensive picture of the severity of the problem of pesticides in drinking water on a nationwide basis. Many agricultural areas were not sampled by these studies and thus are not represented in the results. In addition, some of the studies included in the interim report were not limited to wells used for drinking water supplies but included shallow monitoring wells and wells used only for irrigation.

Copies of the interim report are available from the EPA Public Information Center, PM-211B, US EPA, 401 M Street SW, Washington, D.C. 20460. Telephone: (202) 475-7751.

The results of the National Pesticide Survey of Drinking Water Wells, scheduled for completion in 1990, are expected to meet the need for a statistically representative estimate of pesticide contamination of drinking water wells on a nationwide scale. The Survey will test 1,350 community and domestic wells for over 100 pesticides and breakdown products.

Physician Ratings of Appropriate Indications for Three Procedures: Theoretical Indications vs Indications Used in Practice

ROLLA EDWARD PARK, PHD, ARLENE FINK, PHD, ROBERT H. BROOK, MD, SCD, MARK R. CHASSIN, MD, KATHERINE L. KAHN, MD, NANCY J. MERRICK, MD, JACQUELINE KOSECOFF, PHD, AND DAVID H. SOLOMON, MD

Abstract: We previously reported substantial disagreement among expert physician panelists about the appropriateness of performing six medical and surgical procedures for a large number of theoretical indications. A recently completed community-based medical records study of about 4,500 patients who had one of three procedures—coronary angiography, upper gastrointestinal endoscopy, and carotid endarterectomy—shows that many of the theoretical indications are seldom or never used in practice. However, we find that there is also substantial disagreement (5, 25, or 32 per cent for angiography, endoscopy, or endarterectomy, respectively) about the appropriateness of indications used in actual cases if disagreement is defined by first discarding the two extreme of nine ratings, then looking for at least one rating near the bottom (1 to 3) and one near the top (7 to 9) of the 9-point scale. Patients should know that a substantial percentage of procedures are performed for indications about which expert physicians disagree. (*Am J Public Health* 1989; 79:445–447.)

Introduction

We previously reported on ratings by panels of physicians of the appropriateness of a large number of detailed indications for the use of six medical and surgical procedures.[1,2] The panelists assigned appropriateness ratings to indications in a process that was designed to encourage but not to require agreement. We found that, even in their final ratings, the panelists disagreed about the appropriateness of substantial fractions of the indications. One possible reason for the disagreement is that disagreed-upon indications may not occur in practice; our comprehensive lists included many indications that might be used only in theory.

Our purpose in this paper is to compare the panelists' agreement and disagreement about the theoretical indications with their agreement and disagreement about the indications actually assigned to cases in a recently completed medical records study.[3–5] That study determined the actual reasons for doing three of the procedures (coronary angiography, diagnostic upper gastrointestinal endoscopy, and carotid endarterectomy) in several thousand actual cases in five large areas of the United States. In this paper, we also compare the distribution by appropriateness or inappropriateness of the theoretical indications with that of the actual cases.

Methods

We have previously described in detail our two-stage modified Delphi process for obtaining appropriateness ratings.[1,2] The process used nationally representative panels consisting of nine expert physicians, including both generalists and specialists. The ratings on a nine-point scale ranged from extremely inappropriate (1), through equivocal (5), to extremely appropriate (9). Here we adopt the same four definitions of agreement that we previously used:

A9S: All nine of the ratings fell within a single three-point region—1 to 3, 4 to 6, or 7 to 9.

A9R: All nine of the ratings fell within *any* three-point range.

A7S: After discarding one extreme high and one extreme low rating, the remaining seven ratings all fell within a single three-point region—1 to 3, 4 to 6, or 7 to 9.

A7R: After discarding one extreme high and one extreme low rating, the remaining seven ratings all fell within *any* three-point range.

We also adopt the four previously used definitions of disagreement, and add a fifth. We used the fifth definition in our initial report of the medical records study:[4]

D9S: Considering all nine ratings, at least one was a 1 and at least one was a 9.

D9R: Considering all nine ratings, at least one fell in the lowest three point region (1 to 3) and at least one fell in the highest (7 to 9).

D7S: After discarding one extreme high and one extreme low rating, at least one of the remaining seven ratings was a 1 and at least one was a 9.

D7R: After discarding one extreme high and one extreme low rating, at least one of the remaining seven ratings fell in the lowest three point region (1 to 3) and at least one fell in the highest (7 to 9).

D5R: After discarding two extreme high and two extreme low ratings, at least one of the remaining five ratings fell in the lowest three point region (1 to 3) and at least one fell in the highest (7 to 9).

Deciding what to count as disagreement is necessarily subjective. We added definition D5R and used it in reporting the results of the medical records study[3] after examining patterns of individual panelist's ratings for representative indications. Many patterns that D7R would classify as disagreement, but D5R would not, seemed to us to show substantial clustering around the median rating—enough clustering so that we did not at that time want to count them as disagreement. We include all five definitions here so that readers can make their own choices.

In addition, we use our previous definitions of three appropriateness categories:[2]

Appropriate: a median rating of 7 to 9 without disagreement (using D7R to define disagreement for this purpose in this paper).

© 1989 American Journal of Public Health 0090-0036/89$1.50

Inappropriate: a median rating of 1 to 3 without disagreement.
Equivocal: a median rating of 4 to 6 without disagreement, or any median rating with disagreement.

During the medical records study, we abstracted hospital and office records for random samples averaging about 1,500 cases for each of the three procedures. The patient population consisted of people over age 65 covered by Medicare Part B. From the detailed abstracts, we determined which indication or indications applied to each case; if more than one indication applied, we chose the one with the highest median rating as the primary indication.

We compared the panelists' ratings of the full lists of indications that theoretically could occur, with their ratings of indications assigned to cases that actually did occur in practice. For each case, we noted the primary indication, and what category that indication fell into: agreement or disagreement; appropriate, equivocal, or inappropriate. We then calculated the per cent of cases whose primary indication fell into each category.

Note that the same ratings were used for the theoretical indications and for the actual cases; the panels did not separately rate the actual cases. The comparison we make in this paper is between an unweighted average for all of the indications on the theoretical list, and a weighted average in which each indication is weighted by the number of actual cases for that indication.

Results

Only a small number of indications for each procedure accounted for most of the cases found in the medical records study (see Appendix Table A). For example, the single most frequently occurring indication for angiography (preoperative evaluation of patients undergoing cardiac valvular surgery) accounted for 18 per cent of all cases. (See reference 3 for other frequently occurring indications.) The eight most frequently occurring indications (2.7 per cent of the 300 indications on the theoretical list) accounted for over half of the cases. The other two procedures exhibited similar concentration. We found only 20 to 40 per cent of the theoretical indications to occur at all in our samples of about 1,500 cases for each procedure.

Table 1 shows the percent of agreed-upon indications using each of the four definitions of agreement. The comparison of agreement on theoretical indications with agreement on indications assigned to actual cases is different for the three procedures.

- For angiography, the per cent of agreed-upon indications is about the same for the theoretical list as it is for the actual cases.
- For endoscopy, agreement on cases is substantially higher than is agreement on theoretical indications.
- For endarterectomy, agreement on cases is substantially *lower* than is agreement on theoretical indications.

As defined by A7R, agreement on the appropriateness of indications assigned to actual cases ranged from over 60 per cent for angiography to under 30 per cent for endarterectomy.

Table 2 shows disagreed-upon indications using each of the five definitions of disagreement. Disagreement on cases, compared with disagreement on the theoretical indications, was somewhat lower for angiography, about the same for endoscopy, and substantially higher for endarterectomy. As defined by D7R, disagreement on indications for actual cases was 5 per cent for angiography, but was 25 per cent for endoscopy and 32 per cent for endarterectomy.

Table 3 categorizes theoretical indications and indications assigned to actual cases by level of appropriateness. For all three procedures, the per cent of appropriate cases was higher than the per cent of appropriate theoretical indications—substantially higher for endoscopy and endarterectomy. The per cent of inappropriate cases was about the same

Clearly appropriate						
Median 7–9						
without disagreement	62.3	74.0	21.9	61.3	9.7	32.7
Standard error	(2.8)	(1.1)	(1.3)	(1.2)	(1.0)	(1.3)

Notes. Disagreement means at least two 1–3 ratings and at least two 7–9 ratings. Indic denotes the theoretical indications on the entire list rated by the panel. Cases denotes actual cases to which indications were assigned in a field study of medical records.

as the per cent of inappropriate theoretical indications for angiography, and much lower for endoscopy and endarterectomy. The fraction of cases done for indications that we categorized as clearly inappropriate based on the panel ratings ranged from 10 per cent for endoscopy, through 17 per cent for angiography, up to nearly 30 per cent for endarterectomy.

The percentages in Table 3 differ somewhat from those that we have reported elsewhere.[3] The reason is that Table 3 is based on disagreement defined by D7R, whereas the earlier report used D5R. We adopt the more easily satisfied definition here in order to provide a new perspective on the appropriateness results previously reported.

Discussion

Disagreement among expert physicians about appropriate indications for doing angiography, endoscopy, and endarterectomy is not limited to theoretical indications that are never done in practice. We found that there was generally almost as much or even more disagreement about the appropriateness of indications assigned to actual cases than there was about the complete lists of theoretical indications. Disagreement about either indications or cases was minimal for coronary angiography on most of our definitions. In contrast, there was substantial disagreement about both the theoretical indications and the indications actually used for endoscopy and carotid endarterectomy. For example, 27 per cent of endoscopies were done for reasons that at least one out of nine panelists rated 1 (extremely inappropriate) and at least one rated 9 (extremely appropriate), and thus count as disagreement on definition D9S. Also, 32 per cent of endarterectomies were done for indications that at least two panelists rated 3 or lower and at least two panelists rated 7 or higher (disagreement on definition D7R).

There is generally more difference between the theoretical indications and the indications assigned to actual cases when they are categorized by appropriateness (Table 3), than when they are categorized by agreement or disagreement (Tables 1 and 2). Particularly for endoscopy and endarterectomy, inappropriate indications occur frequently on the theoretical lists, but most of them are not used in practice.

The high percentages of disagreement about the appropriateness of doing endoscopies and endarterectomies for indications that were assigned to actual cases reflect the real uncertainty about the efficacy of these procedures in many situations.[6,7] Clinical trials may help to lessen the uncertainty in the future, but can never eliminate it entirely. Physicians should carefully weigh the advisability of doing a procedure for indications that lack firm scientific justification. If they do believe that the procedure is advisable in such circumstances, they should make sure that their patients understand that other physicians might disagree. Also, patients should attempt to ascertain and to understand the reasons for their doctor's recommendations before submitting themselves to expensive, invasive procedures.

Beliefs about AIDS as Determinants of Preventive Practices and of Support for Coercive Measures

ROBERT ALLARD, MD, MSc

Abstract: We performed a telephone survey to explore relations between knowledge, beliefs (as defined in the Health Belief Model) and reported AIDS-preventive practices in a sample of 1,072 persons ages 18-65, living in the Montreal health region.

AIDS-preventive practices were more frequent among the young or single, and among those with one of four health beliefs: perceiving oneself as particularly susceptible to AIDS, perceiving the disease as particularly severe, perceiving it as particularly amenable to prevention, and having a strong general health motivation. Support for coercive measures to control the AIDS epidemic was widespread but was stronger among the less educated, married people, and those with a high level of one of the following beliefs about AIDS: perceived severity, susceptibility, curability, or barriers to treatment.

AIDS-preventive practices and support for coercion under epidemic conditions share their most important modifiable determinants: perceived severity of AIDS and perceived susceptibility to it. This finding suggests that emphasizing them, as is done so often in public educational campaigns about AIDS, may indeed promote preventive practices, but may also unwittingly increase support for coercive measures toward people with the disease or at high risk of it. (*Am J Public Health* 1989; 79:448–452.)

Introduction

Although the incidence of the acquired immunodeficiency syndrome (AIDS) has remained low outside of the recognized high-risk groups,[1] concern about an eventual increase in transmission among groups now at low risk has led to large-scale information programs promoting AIDS-preventive practices in the general population. Studies of practices intended to reduce the risk of AIDS in various groups have been extensively reviewed.[2] Although information is available about these in some high-risk groups (homosexual men, intravenous drug users, hemophiliacs, single heterosexual men, heterosexual partners of HIV (human immunodeficiency virus)-positive persons, adolescents and young adults, prostitutes and their clients) relatively little is known about preventive practices in the general population.

The theoretical model that has guided the design of any published studies,[3] the Health Belief Model (HBM),[4] makes it indeed attractive as a theoretical approach to AIDS-related behavior. Scales of demonstrated validity and reliability have been developed, using standard psychometric methods, for measuring health beliefs.[5–7]

The objectives of the present study were to:

- describe how knowledge, beliefs and practices related to AIDS are distributed among the general population of the Montreal health region, including all French- and English-speaking persons 18-65 years of age;
- identify associations between AIDS-preventive practices and sociodemographic characteristics, knowledge and health beliefs of this population.

Methods

The Questionnaire*

The sociodemographic variables included sex, age, educational level, mother tongue, marital status, and total household income.

Knowledge was measured by scales on AIDS symptoms (six items), modes of transmission (six items), and high-risk groups (eight items). Each scale had equal numbers of true and false statements; agreeing with a true statement added one point to the score for the scale, as did disagreeing with a false one; the opposite choices resulted in the loss of a point.

Health beliefs were measured by six Likert-type scales: perceived severity of AIDS (five statements with which the respondent had to express his degree of agreement or disagreement), perceived susceptibility to it (five statements), perceived benefits of its prevention (six statements), perceived benefits of its treatment (five statements), perceived barriers to its treatment (two statements), and general health motivation (six statements). The scales measuring severity, susceptibility, and general health motivation were borrowed from Champion,[7] substituting "AIDS" for "breast cancer"; the others were created by the investigator on the same model. All scales showed a high degree of internal consistency (in a pretest using a convenience sample of persons attending a travelers' immunization clinic), after statements poorly correlated with the total score for their scale had been eliminated.

AIDS-preventive practices were probed by 14 questions: five on changes in sexual behavior, four on health care sought or avoided, and one each on substance abuse, avoidance of social contacts, precautions at work, condom use, and avoidance of blood donations.

Support for coercive measures was assessed by questions on whether the respondent would support each of four types of coercive actions by the government to control the AIDS epidemic.

The Survey

The data collection was carried out by a major telephone polling agency using random digit dialing. Standard procedures determined the generation of telephone numbers, the random selection of the respondent within the household (no substitution allowed), the number of calls to be made in case of non-response, and call-backs for quality control.

The univariate statistical analyses were done by contingency tables, after all variables had been dichotomized. The 95% confidence intervals (CI) of the odds ratios (OR) were calculated by the test-based method.[8] All potential determinants of preventive practices and of support for coercive measures were also subjected (separately) to logistic regres-

sion analyses, using program BMDPLR with the default options in force. An attempt was made to introduce into the equation interactions between the most important terms. ORs and their 95% CIs were calculated from the regression coefficients in the usual way.[8] The comparison between two ORs when one is larger and the other smaller than unity is made easier by taking the reciprocal of one of them (thus inverting the high- and low-risk categories).

Results

Response Rate

A total of 2,677 telephone numbers were generated, of which 64 per cent (1,712) belonged to the target population (i.e., the numbers were in service, residential, and reached a household with at least one member meeting the age and language criteria). Of the 1,712 eligible respondents, 63 per cent (1,072) were interviewed. Non-response was due to refusal or repeated absence of the respondent selected within the household (29 per cent and 4 per cent, respectively) or to the impossibility of reaching anyone at the number (4 per cent). The interviews were done between March 25 and May 24, 1987.

Description of the Sample

Forty-two per cent of respondents were men and 58 per cent women; 18 per cent were between ages 18 and 24, 16 per cent between 25 and 29, 25 per cent between 30 and 39, 18 per cent between 40 and 49, and 23 per cent were age 50 or over. The mother tongue was French for 70 per cent, English for 18 per cent, and other for 12 per cent; 79 per cent of interviews were carried out in French, the rest in English. Fifty-two per cent of the respondents were married or living in a common-law relationship, 32 per cent were single, 13 per cent were separated or divorced, and 3 per cent were widowed. The highest education level attained was grade school for 7 per cent, high school for 43 per cent, junior college for 20 per cent, and university for 30 per cent. Total household income was below $20,000 (Canadian) for 31 per cent, and above $40,000 for 26 per cent.

Knowledge

Almost all respondents (98.6 per cent) had heard of AIDS. Knowledge of the modes of transmission was highest, with 81 per cent of respondents having the maximum possible score; knowledge of high-risk groups was intermediate and that of AIDS symptoms lowest, its mean being in the middle of the possible range. All measures of knowledge about AIDS were higher among the more educated, as has been reported for other aspects of health knowledge.[9]

Health Beliefs

As a whole, the distributions of health beliefs were not as skewed as those of knowledge. Only four strong associations between health beliefs and sociodemographic characteristics were detected: women have a higher general health motivation than men, unmarried persons (even when controlling for younger age) have a higher perceived susceptibility to AIDS than married persons, better-educated and French-speaking persons have a higher perceived preventability of AIDS. Apart from these instances, beliefs about AIDS appear to be uniformly distributed among basic social groups.

AIDS-Preventive Practices

Sixty-nine per cent of respondents denied all of the 14 practices asked about, 15 per cent acknowledged one, 8 per cent, two, 4 per cent three, and 4 per cent between four and nine; in all, 31 per cent acknowledged at least one practice. The frequencies of the most common practices were:

- voluntarily decreasing the number of sex partners (13 per cent);
- changing one's sex behavior (12 per cent);
- using a condom to avoid the transmission of AIDS (10 per cent);
- avoiding social contact with certain people or groups, mostly homosexuals, prostitutes, and casual sex partners (6 per cent);
- taking precautions at work, such as health care workers wearing gloves, masks or blouses, washing hands, handling needles carefully, taking precautions in relation to eating or avoiding certain people (6 per cent);
- avoiding certain types of sexual behavior, including vaginal intercourse (1.7 per cent), oral intercourse (2.2 per cent), and anal intercourse (2.4 per cent);
- avoiding giving blood (4 per cent);
- visiting a doctor because of AIDS (2 per cent);
- refusing to receive a blood transfusion (1 per cent)
- five other practices (less than 1 per cent each).

Unfortunately, too little is known about the respondents to assess whether each practice acknowledged by each respondent was indicated or superfluous for this individual, except for the completely ineffective practices.

Support for Coercion

Four questions on the issue of coercion and the answers given were as follows:

"Do you think children with AIDS should attend school in the same way as other children?" Yes 70%, no 20%, don't know 10%.

"Do you think the government should declare illegal certain kinds of sexual activity, if this helps fight the AIDS epidemic?" Yes 40%, no 50%, don't know 10%. Types of sexual activity most often mentioned: homosexuality (14% of all 1072 respondents) and prostitution (7%).

"Do you think that people with AIDS should be prevented from holding certain kinds of jobs, if this helps fight the AIDS epidemic?" Yes 44%, no 45%, don't know 10%. Jobs most often mentioned: those in hospitals or in the medical field (13%), involving contact with the public (6%), in the food industry or in restaurants (6%).

"Do you think that certain groups of people should be forced to take a test to find out if they have AIDS, if this helps fight the AIDS epidemic?" Yes 74%, no 21%, don't know 4%. In all, 23 groups were named; most commonly: homosexuals or bisexuals (23% of all respondents), everyone (11%), and prostitutes (5%).

The number of questions for which the respondent chose the "coercive" answer can be considered a variable indicative of the strength of his support for coercive measures to control AIDS, on a scale of 0 to 4. The percentages of respondents in each category were respectively 14, 31, 27, 21 and 8 per cent. In subsequent analyses, subjects in the last two categories will be considered to support coercion, those in the first two not to support it, and those in the third will be left out of the analyses.

Determinants of Preventive Practices and of Support for Coercion

Table 1 presents the percentage of respondents having carried out at least one preventive practice, when each potential determinant is present and absent, with the corresponding ORs and their 95 per cent CIs. Being young, male, single, of high education, of low income, perceiving AIDS as

TABLE 1—The Determinants of AIDS-Preventive Behavior*

Curability	30.6	30.7	1.00	(0.76, 1.32)
Barriers	29.1	32.6	0.85	(0.65, 1.10)
General Health Motivation	33.5	27.2	1.35	(1.03, 1.75)

*Percentage of subjects having carried out at least one preventive practice, in the presence and absence of each potential determinant, with the corresponding odds ratio and 95% confidence interval. (N = 1050).

a particularly severe illness, perceiving oneself as particularly susceptible to AIDS, or having a high general health motivation are all significantly associated with having carried out at least one preventive practice. Interestingly, knowledge is not a determinant.

Table 2 presents in a similar way the determinants of support for coercion. Support is more common in those who are older, married, of low education or low income, with a poor knowledge of the modes of transmission or of high-risk groups or having a high level of one or more of these beliefs about AIDS: perceived severity, susceptibility, preventability, and barriers to treatment.

There also are many associations among the determinants themselves, so that the effects presented in the two previous tables cannot be considered independent of each other. Logistic regression was used to unravel these relations. The resulting models are presented in Table 3.

The determinants of having carried out a preventive practice no longer include education or income, probably because these are strongly associated with age. Sex is also eliminated, by a hair's breadth, probably because of its association with the health beliefs. Having a high perceived preventability of AIDS becomes significant.

The determinants of support for coercion no longer include age, income, or any of the knowledge measures, probably because of their association with education. Perceived preventability loses its significance, while perceived curability becomes significant.

In neither case was there any interaction between the most important terms of the regression equation.

One notes that the two outcomes share their most important modifiable determinants (perceived severity and susceptibility). Indeed, the two outcomes are associated: a support for coercion is present among 45 per cent of respondents who have carried out one or more practice and in 37 per cent of those who have not done so.

TABLE 2—The Determinants of Support for Coercive Measures*

Determinants	Present	Absent	OR	(95% CI)
Demographics				
Age (< 35)	36.1	43.9	0.72	(0.54, 0.97)

Curability	42.9	36.7	1.29	(0.97, 1.73)
Barriers	44.8	33.5	1.61	(1.20, 2.16)
General Health Motivation	41.8	37.7	1.19	(0.89, 1.59)

*Percentage of subjects with a high degree of support, in the presence and absence of each potential predictor, with the corresponding odds ratio and 95% confidence interval. (N = 723)

One notes that the two outcomes share their most important modifiable determinants (perceived severity and susceptibility). Indeed, the two outcomes are associated: a support for coercion is present among 45 per cent of respondents who have carried out one or more practice and in 37 per cent of those who have not done so.

Discussion

A response rate of 63 per cent is close to the average rate of 65 per cent reached by the agency for telephone surveys in the Montreal region; how non-respondents differ from respondents, and whether this could have affected the results obtained, is unknown. Most respondents were French-speaking, but language influenced neither the frequency of practices nor support for coercion, so that the results appear generalizable to English-speaking populations.

A purely cross-sectional study cannot establish the time-relations in the associations it detects, and thus provides no grounds for deciding whether the associations are causal or not. Neither knowledge nor beliefs necessarily precede the behavior with which they are associated. They *may* have helped bring it about; or they may have resulted from it, people selectively acquiring knowledge and beliefs consistent with behavior that has already been determined by quite different influences. The likelihood of this having happened is

perhaps less for a new disease like AIDS than for one people have known for most of their lives.

It may seem surprising that 31 per cent of respondents reported some behavioral adaptation to the AIDS epidemic, but the proportion is in fact close to that found in studies of adolescents[10] or of the Canadian population.[11]

Unfounded practices are less frequent than appropriate ones, although not as rare as one would wish. The most frequent ones are avoidance of social contacts (6 per cent) and of donating blood (4 per cent). These remain pertinent targets for specific educational efforts.

The formulation of the four questions on support for coercion calls for some comments. The question on school attendance is the only one for which a "yes" answer (which, everything else being equal, respondents prefer to give—the "acquiescence response set") meant a non-coercive stand. This may be a reason why the answers to it favored coercion much less than those to the other questions. A more encouraging reason might be that the issue of school attendance has arisen concretely, has been discussed in the media, and has sometimes given rise to constructive and compassionate reactions. The other three questions all end with "if this helps fight the AIDS epidemic." This clause (including the emotionally charged word "epidemic" which would usually be avoided in questionnaire formulation) was added in order to simulate these measures being advocated. Presumably, they would be touted as necessary to fight the epidemic, not as a novel way to oppress people. Hence the answers should be interpreted as a measure of latent rather than actual support for coercion, except perhaps for respondents who believe themselves to be in the midst of an AIDS epidemic.

The high level of support for coercive measures detected in this survey corresponds to the findings of previous studies. Mandatory testing is widely supported, whether it be for everyone (52 per cent of Americans in favor)[12] or for high-risk groups (about two-thirds of Canadians in favor).[11] However, in this study, there is little agreement on who these measures should apply to. Such "free floating" support may be more easily counteracted if it is not given time to crystallize around specific measures against specific groups.

A methodological note of caution—odds ratios are used as measures of effect because they can be computed from logistic regression coefficients. However, neither dependent variable is rare (practices in 31 per cent of 1,050 respondents, support for coercion in 40 per cent of 723 subjects in this analysis), so that the OR tends to overestimate the size of the effect. The magnitude of this phenomenon can be estimated by taking the ratios of the percentages presented in Tables 1 and 2 and comparing these rate ratios with the corresponding ORs.

The absence of significant interactions between determinants indicates that the effect of a given change in health beliefs would not be significantly different in any subgroup (whether defined by age, sex, marital status, or income). Thus this survey provides no evidence suggesting that one should try and modify some beliefs in some groups and other beliefs in other groups. Obviously, there will be groups with strong sets of beliefs about AIDS which differ from those of the general population (such as gay men, hemophiliacs or IV drug users) but the survey was not aimed at them.

As for the groups that the study did identify, it is easy to understand why the young and the unmarried have adopted AIDS-preventive practices more frequently than the others (even though information on their usual sexual activities is unavailable); this corresponds to the findings of American surveys.[13] The higher frequency in men (32 per cent) compared to women (24 per cent) is puzzling, other determinants being equal as estimated from the regression equation (unadjusted figures are 36 and 27 per cent). Assuming that 5 per cent of men are homosexual, that 100 per cent of homosexual men have adopted at least one preventive practice and that the same proportion of heterosexual men and women have adopted a preventive practice, one can compute that in all 28 per cent of men would have adopted a practice:

$$(1.00 \times 0.05) + (0.24 \times 0.95) = 0.28.$$

This is the mid-point between the observed proportions in men and women. Thus homosexuality in men can explain up to half of the difference between the sexes, but the other half is unaccounted for, since other measured determinants have been taken into account in calculating these percentages. Thus there appears to be a lag in the acceptance of preventive practices by women in this survey, contrary to what is reported in the US.[13]

It has been suggested that willingness to support coercive measures is associated with having false information about the transmission of HIV.[14] In this survey, having agreed with false statements about transmission is indeed strongly predictive of support for coercive measures, in univariate analyses, but, as in the case of knowledge scores, the effect does not hold up in multivariate analyses. These results fail to confirm the existence of a relation between misconceptions about transmission and support for coercion.

Finally, the finding that preventive practices and support for coercion share the same important modifiable determinants is probably the most thought-provoking result of this study. Many health education messages aim precisely at creating fear of AIDS and feelings of vulnerability to it. Such messages may increase support for coercion as well as foster preventive behavior. Let us not forget the warnings about the counterproductive effects of excessive levels of fear,[15] and about the importance of complementing messages on the severity and probability of an untoward health event with information about the effectiveness of preventive action[16] and with positive reinforcement of desirable forms of behavior.[17] In this respect, it is worth noting that a strong belief in the preventability of AIDS was associated (although weakly) with having adopted at least one AIDS-preventive practice, but not with supporting coercive measures.

Clearly, the many health educational efforts made to contain the AIDS epidemic need to be guided by a better knowledge of all their consequences, whether intended or not. The Health Belief Model appears useful for generating this knowledge.

Accuracy of Cholesterol Level Tests Should be Double-Checked

A single test may not accurately reflect a person's cholesterol level, and errors can result in significant differences in medical treatment, according to the February issue of the *Tufts University Diet & Nutrition Letter*. Part of the problem is that many laboratories as well as manufacturers of cholesterol testing equipment have not been using the same test methods, and/or have not been setting their equipment to the standard established by the National Cholesterol Education Program of the National Institutes of Health.

A 1985 study done by the College of American Pathologists found that readings may be off as much as 15 percent, meaning that someone with a true reading of 220 milligrams per deciliter of blood could be told their cholesterol level is from 187 to 253. With a level of 200 considered desirable, misreadings can mean the difference between a clean bill of health and a diagnosis of being at risk for heart disease. But laboratories and manufacturers are making changes. And by asking the right questions, individuals can ensure the accuracy of their own readings before deciding on new dietary regimes.

Herbert K. Naito, chairman of the Laboratory Standardization Panel of the National Cholesterol Education Program, noted that the dozen manufacturers who produce about 75 percent of cholesterol testing equipment in the United States are calibrating their equipment according to national standards.

In addition, the Centers for Disease Control in Atlanta have set up a network of reference laboratories that use the accepted standardization so that other labs can check the accuracy of their analyses.

Preventing AIDS and Other STDs through Condom Promotion: A Patient Education Intervention

MILDRED Z. SOLOMON, MA, AND WILLIAM DEJONG, PHD

Abstract: We report on two studies that assessed the impact of a soap-opera style videotape on inner-city STD (sexually transmitted disease) patients' knowledge about and attitudes toward condom use, and willingness to redeem coupons for free condoms. Subjects in the first study who viewed the videotape (and participated in a brief oral recall session) had higher knowledge scores and more accepting attitudes than subjects who did not (knowledge test means of 11.1 versus 7.9, attitude index means of 13.0 versus 11.3). The intervention was most effective among those who were relatively poorly educated and, to a lesser extent, among those who reported less frequent use of condoms and fewer sex partners. In the second study, intervention group subjects were more likely than control group subjects to redeem coupons. Both groups exhibited a high level of interest in the free condoms. We argue that education *and* accessibility to free condoms can increase condom use and that health care providers have a vital role in promoting this form of STD prevention. (*Am J Public Health* 1989; 79:453–458.)

Introduction

Condom use appears to be one of the most important weapons in the public health fight against AIDS (acquired immunodeficiency syndrome).[1-3] Campaigns to promote condom use have been launched within the gay community[4] and among prostitutes,[5] but much more needs to be done, especially to reach the drug-using population, female partners of drug-users and bisexuals, individuals with multiple sex partners, and minority populations.[2-5]

Although the AIDS crisis has spotlighted national attention on the need for condoms, the US Public Health Service called for an increase in condom use in 1980,[6] well before AIDS was the national public health priority it is now. Both laboratory studies of condom permeability and epidemiological field studies of disease incidence among those who do and do not use condoms have documented that condoms are effective against a wide variety of sexually transmitted diseases (STDs) including gonorrhea,[7,8] nongonococcal urethritis,[9,10] trichomoniasis,[10,11] and herpes genitalis,[12,13] as well as AIDS.[14,15] Although one recent review of the literature suggests that clinical evidence for the condom's effectiveness against AIDS is less than conclusive,[16] public health authorities have called for the use of condoms by individuals at high risk.[17] Despite their promotion, however, condoms are underutilized, especially among individuals who are most at risk, such as persons with multiple sex partners,[10,18] or those who have been previously treated for an STD.[19]

Historically, condom use in the US has been associated with extramarital sex, prostitution, and promiscuity.[20-22] In addition, condoms are perceived by both men and women to impair the pleasure of sexual intercourse.[23-25] Furthermore, introducing condom use can entail a difficult interpersonal negotiation that can result in distrust and embarrassment.[26]

Prior to the AIDS crisis, there were very few concerted efforts by the public health community to promote condom use in the United States. The paucity of domestic condom promotion efforts stands in sharp contrast to the large-scale public education campaigns undertaken abroad in both developing and industrialized countries[20,27-29] for birth control purposes and for STD prevention.[30] These campaigns have often employed social marketing techniques, promoting positive images of condoms while providing greater accessibility to them through, for example, more convenient purchase outlets and subsidized prices. Recent pressure on the national television networks in the US to air condom advertisements suggests that, with continuing public concern about AIDS, we may eventually see large-scale social marketing of condoms in this country.

We conducted two studies to ascertain the effects of a patient education videotape and an oral recall session on patient's knowledge about the need for condoms and their proper use, attitudes toward condoms, and motivation to redeem coupons for free condoms. We also studied whether the intervention was more successful with different patient subgroups. The procedures for both studies were reviewed and approved by the Institutional Review Board of Education Development Center, Inc.

The Videotape

The videotape, entitled "Let's Do Something Different," follows the story of Diane, a young Black woman who has had two cases of gonorrhea and recently returned from the hospital after a bout of pelvic inflammatory disease. Through the support of her brother and a girlfriend, Diane comes to realize that she can persuade her boyfriend to use condoms, and we see her communicate with him successfully, with good grace and humor. Several features of the videotape merit attention:

- *The videotape portrays using condoms as socially acceptable, normative behavior.* The protagonist's growing confidence that she can influence her lover is due to the persistent advice of her brother and girlfriend, both of whom are sexually attractive and sexually active, yet committed to the values of health and sexual responsibility. The brother, and later the converted boyfriend, serve as role models for male viewers by providing examples of men who understand the severity of STDs and who are comfortable expressing their love and concern for a woman they care about.
- *The focus is on the development of interpersonal and communication skills.* The videotape presents only the most essential factual information about disease etiology and transmission. Furthermore, "safe sex" is promoted not by graphic depictions of sex acts, but by modeling effective communication styles and conflict

resolution—those interpersonal skills required for negotiating safe sex with one's partners.

- *The protagonist is a woman.* A consequence of asymptomatic venereal infection in women, pelvic inflammatory disease (which often results in sterility) is endemic in the U.S., with 857,000 cases reported per year.[30] Black women bear a disproportionate burden, with a rate nearly three times that for White women.[31] We chose a female protagonist and a feminine point of view for our narrative in order to highlight the heavy toll that unprotected intercourse takes on the reproductive health of women. We hoped that, by coming to understand the consequences of unprotected intercourse on women and children, men (who constitute the vast majority of patients seen in most public clinics) would be more motivated to change their own attitudes and behaviors.
- *It strives to create a sense of identification within viewers.* Since the videotape is intended primarily for use in public clinics that serve a predominantly Black population, most of the characters are Black and they express many of the same attitudes, beliefs, and values that our background research revealed to be important to this patient population. The script purposely avoids the use of medical terms, using instead the argot of the target group.
- *The videotape attempts to make condoms more sexually appealing.* Although it acknowledges their disadvantages, the videotape refers to the ways in which condoms can enhance sexual pleasure—by prolonging intercourse[32]; by their slight tourniquet effect on the superficial veins of the penis, which may help sustain erection[32]; and by giving both partners peace of mind.[23] Also, because of the widespread complaint that condoms are disruptive, the videotape suggests that putting the condom on can be integrated into foreplay. "Eroticizing" the condom in this way is consistent with the tenets of social marketing,[20,33,34] which hold that target behaviors should be associated with existing values and desires already held by the audience.

STUDY 1: KNOWLEDGE AND ATTITUDES

Method

During the spring of 1986, clinicians at the STD Clinic at Boston City Hospital referred to the study all patients seen at the clinic except those who were under 18 years of age, were non-English speaking, had returned for a test-of-cure examination, or needed to be examined by a specialist. A total of 214 patients were referred. Of those, our research assistant had to pass over 59 to avoid excessive clinic backlog; eight were absent when called; four were non-English speaking; 10 were under 18 years of age and could not be in the study; and four had been seen previously.

While each potential subject waited to receive his or her laboratory test results, the research assistant explained the purpose of the study and solicited his or her informed consent to participate. Of the 129 patients asked, 103 (79.8 per cent) agreed to participate. Half of the consenting subjects were assigned randomly to see the videotape (intervention group, n=51); half were not (control group, n=51). All subjects in the intervention group viewed the videotape individually.

Measurement

All subjects were asked several questions about their demographic background, STD history, number of sexual partners in the past month, and estimated frequency of condom use (never, almost never, sometimes, most times, all times).

Intervention group subjects were shown the videotape and, immediately after viewing, were asked to recall its main points. As the subjects talked, the research assistant checked off on a master list which points were recalled and wrote out additional points mentioned if they did not appear on the checklist; general probes (e.g., Anything else? Can you think of anything more?) were used until subjects had nothing more to add.

Both intervention and control group subjects took a 13-item true-false test, administered by the research assistant. All of the test items were derived from the content of the videotape. Item number 13 had a negative item-total correlation and was omitted from further analysis. The remaining 12 items showed good internal reliability (coefficient alpha =.64). Subjects were also asked 14 additional true-false questions designed to measure their attitudes toward condom use. An attitude index derived from these 14 true-false items showed good internal reliability (coefficient alpha =.66).

Subjects then were asked the following open-ended question: "If a person wants to convince his/her sex partners to use condoms, what are some things that person could do or say?"

Patient Profile

Study subjects were predominantly male (81.6 per cent), single (74.8 per cent), Black (79.6 per cent), and native-born (78.4 per cent). Subjects ranged in age between 18 and 51 years (median = 24 years); 77.5 per cent were 30 years or younger; 24.3 per cent had completed only junior high, 36.9 per cent had completed only high school, and 36.9 per cent had attended college or a vocational/technical school.

Sixty-four per cent of the subjects had a prior history of sexually transmitted disease, and about one-fifth reported a diagnosis within the last six months. Just under half of the subjects reported having more than one sex partner during the past month. Fifty-eight per cent of subjects reported that they had never or almost never used condoms prior to their present visit.

Intervention and control groups did not differ with respect to sex, marital status, race, age, education, birthplace, prior STD history, number of sex partners in the past month, or previous condom use.

Results

Patients' Knowledge and Beliefs

Table 1 presents the percentage of intervention and control group subjects who responded correctly for each item of the true-false test. Subjects who saw the videotape scored higher than subjects who did not: 70.6 per cent of the intervention group correctly answered 11 or all 12 items; only 7.7 per cent of the control group subjects scored that well.

Patients' Attitudes

Table 2 presents the percentage of intervention and control group patients who indicated a favorable response for each item of the attitude index. The mean score on the attitude index was higher for the intervention group (13.0) than the control group (11.3), indicating a more favorable attitude toward condom use among subjects who saw the videotape. While 70.6 per cent of intervention group subjects answered 13 or 14 of the attitude items favorably, only 32.7 per cent of the control group patients did so.

Strategies to Persuade Partners to Use Condoms

As shown in Table 3, intervention group subjects cited more strategies for persuading partners to use condoms, exclusive of citing the condom's effectiveness in preventing pregnancy and disease. The most commonly mentioned alternative strategies included: refusing to have sex; and citing that using condoms could be fun and did not have to interfere with lovemaking.

TABLE 1—Percentage of Patients with Correct Response on Each Item of the Knowledge Test by Experimental Condition

Knowledge Test Items*	% Correct Responses			
	Intervention Group	Control Group	Difference	(95% CI of Difference)
1. Using a condom can help make intercourse last longer. (T)	94.1	36.5	57.6	(43.0, 72.2)
2. It's a good idea to use Vaseline for lubrication when using a condom. (F)	98.0	53.8	44.2	(30.1, 58.3)
3. If a woman is on the pill, her sex partners don't need to bother wearing a condom. (F)	98.0	61.5	36.5	(22.7, 50.3)
4. Some men never get symptoms for sexually transmitted disease. (T)	70.6	36.5	34.1	(16.0, 52.2)
5. For most sexually transmitted diseases, women usually get symptoms or early warning signs. (F)	84.3	51.9	32.4	(15.5, 49.3)
6. The condom should be unrolled before attempting to put it on the man's penis. (F)	88.2	61.5	26.7	(10.8, 42.6)
7. A condom should be worn so that it's snug at the tip. (F)	88.2	63.4	24.8	(9.0, 40.6)
8. The only way to make sure of preventing sexually transmitted disease is to use a condom every time. (T)	100.0	78.8	21.2	(10.1, 32.3)
9. When a person has more than one sex partner, it is impossible for that person to know for sure which partner was the source of the infection. (T)	90.2	71.2	19.0	(4.2, 33.8)
10. If a woman has a pelvic inflammatory disease (PID) more than once, she can become sterile and not be able to have children. (T)	98.0	80.8	17.2	(5.9, 28.5)
11. When a person has a sexually transmitted disease, that person should notify every sex partner he or she has had within the last month to get treatment. (T)	100.0	98.1	1.9	(−1.8, 5.6)
12. A person who has a sexually transmitted disease but no symptoms can still pass on that disease to other people. (T)	100.0	98.1	1.9	(−1.8, 5.6)
13. A man doesn't need to put on a condom until he's ready to come or ejaculate. (F)**	98.0	100.0	−2.0	(−5.8, 1.8)
Total Score (Estimated Mean)	11.1	7.9	3.2	(2.7, 3.7)

*Correct answers indicated in parentheses. T = True and F = False.
**This item was not included in the total score calculations.
NOTE: Intervention Group saw videotape; Control Group did not.

Differential Effectiveness of the Intervention

To determine whether the videotape was particularly helpful for subgroups of respondents, we estimated a series of regression models that tested the predictive power of each background characteristic as a main effect and in interaction with the intervention variable. Two sets of models were constructed—one for knowledge and one for attitudes.

When predicting knowledge, three background characteristics interacted with the intervention variable—years of education, previous condom use, and number of sexual partners. Despite correlations among these three background

TABLE 2—Percentage of Patients with Favorable Response on Each Item of the Attitude Index by Experimental Condition

Attitude Test Items*	% Favorable Responses			
	Intervention Group	Control Group	Difference	95% CI of Difference
1. Any man who refuses to use condoms is being selfish. (T)	94.1	61.5	32.6	(17.9, 47.3)
2. More women should get their lovers to use condoms. (T)	100.0	75.0	25.0	(13.2, 36.8)
3. There's no way a man and a woman can make using a condom sexy, even if they have the right attitude. (F)	86.3	63.5	22.8	(6.7, 38.9)
4. I can honestly say that, as a result of my visit to the clinic today, I will be using condoms more often. (T)	86.2	69.2	17.0	(1.3, 32.7)
5. I would not want my friends to know if I used condoms. (F)	90.2	75.0	15.2	(0.9, 29.5)
6. Condoms are not worth the bother. (F)	100.0	88.5	11.5	(2.8, 20.2)
7. A woman who insists that a man wear a condom is being unfair. (F)	96.1	84.6	11.5	(0.3, 22.7)
8. I just couldn't bring myself to talk to my sex partners about using condoms. (F)	94.1	82.7	11.4	(−0.7, 23.5)
9. I could never talk to my friends about whether I should use condoms. (F)	90.2	78.9	11.3	(−2.4, 25.0)
10. It's okay for a woman to carry condoms with her. (T)	94.1	88.5	5.6	(−5.2, 16.4)
11. People who use condoms every single time are being silly. (F)	100.0	96.2	3.8	(−1.4, 9.0)
12. If a friend tried to talk me into using condoms, I'd probably get angry. (F)	88.2	90.3	−2.1	(−14.0, 9.8)
13. Using a condom doesn't have to interfere with lovemaking. (T)	80.4	78.9	1.5	(−14.0, 17.0)
14. It is okay for a man to carry condoms with him. (T)	96.1	96.1	0.0	(−7.5, 7.5)
Total Score (Estimated Mean)	13.0	11.3	1.7	(1.0, 2.4)

*Answers indicating a favorable attitude are indicated in parentheses. T = True and F = False.
NOTE: Intervention Group saw videotape; Control group did not.

TABLE 3—Total Number of Strategies‡ Offered to Persuade Partners to Use Condoms by Experimental Condition

Number of Strategies	Experimental Condition	
	Intervention Group N (%)	Control Group N (%)
0	11 (21.6)	27 (51.9)
1	28 (54.9)	21 (40.4)
2	10 (19.6)	4 (7.7)
3	2 (3.9)	0 (0.0)
Mean*	1.1	0.6
Standard Deviation	0.6	0.4

*Difference between conditions is 0.5, 95% C.I. = 0.2, 0.8.
‡Exclusive of citing the condom's effectiveness in preventing pregnancy and disease.

characteristics, their effects persisted in a multiple regression model, as presented in Table 4 (total R^2=68.6 per cent). Regardless of background characteristics, subjects in the intervention group scored higher than subjects in the control group. Moreover, the videotape was most effective for subjects with less formal education, subjects who had never used condoms, and subjects with only one sexual partner in the past month.

When predicting attitudes, three background characteristics also interacted with the intervention variable—years of education, birthplace, and previous condom use. Because of correlations between previous use and the other two background characteristics, however, the effects of previous use (both main effects and interaction) did not persist in a multiple regression model. Thus, the final model, presented in Table 5, includes only the other two background characteristics (total R^2=44.3 per cent). Regardless of background characteristics, subjects in the intervention group had more favorable attitudes toward condoms than subjects in the control group. The intervention was most effective for subjects with less formal education and for those who were not native born.

STUDY 2: COUPON REDEMPTION

Method

The second study was conducted in the STD clinic at Boston City Hospital in the summer of 1986. As in the first study, clinicians referred all patients seen at the clinic, other than those who were under 18 years of age, were non-English speaking, had returned for a test-of-cure examination, or needed to be examined by a specialist. Of 393 patients referred, 57 were passed over to avoid creating a backlog of patients in the clinic; 32 were absent when called; five were non-English speaking; 25 were under 18 years of age; and 24 had participated previously in study 1 or an earlier pilot test.

Again, patients were seen while they awaited their laboratory test results. Of the 250 patients eligible to participate, 29 said they could not be reached by telephone for a follow-up interview we planned to conduct, and 39 refused to participate, leaving a study of 182 (or 72.8 per cent) of those eligible.

Qualifying patients who consented to participate were assigned at random to see the videotape (intervention group, n=89) or not (control group, n=93). Both groups of patients were given two postcard-sized coupons and told that they could be redeemed for free condoms; to protect patient privacy, the word "condom" did not appear on either coupon. The first coupon could be redeemed that day at another room at the clinic. The second, pre-addressed and stamped, could be redeemed by mail. When patients redeemed a coupon, they were given (or mailed) a packet with six condoms and a one-page information sheet on proper use.

Patient Profile

The subjects participating in this study were similar to

TABLE 5—Predicted Values of Attitude Index from Multiple Regression Model

Education	Birthplace	Attitude Index Scores		Difference

those in Study 1: predominantly male (80.2 per cent), single (85.7 per cent), Black (85.2 per cent), and native born (74.7 per cent). Patients ranged in age between 18 and 73, with a median age of 24; 83.0 per cent of the patients were 30 years of age or younger. Again, educational attainment varied: 18.1 per cent had completed junior high, 43.4 per cent had completed high school, and 37.9 per cent had at least some post-high school education. Two-thirds of the subjects reported a prior history of sexually transmitted disease. Exactly half said they had two or more sex partners within the past month. There were no important differences between the two experimental conditions across all of these background variables.

Results

Coupon Redemption

Across both conditions, 110 (60.4 per cent) of the patients redeemed a coupon at the clinic only; another 25 patients (13.7 per cent) redeemed coupons both at the clinic and by mail; two patients (1.1 per cent) redeemed by mail only; only 45 subjects (24.7 per cent) did not redeem either coupon. Table 6 presents the number of coupons redeemed via clinic and/or mail by condition.

Patients who saw the videotape redeemed a significantly greater number of coupons; more control group subjects redeemed no coupons, while more intervention group subjects redeemed two. A Wilcoxon test yielded a p-value for the difference of .03. A logistic regression model showed that none of the background variables were associated with coupon redemption.

Discussion

Subjects who watched the videotape were more aware of their own susceptibility to STDs and their consequences, the benefits of condom use, the particulars of proper use, and general information on STD transmission than were subjects who did not see the videotape. Furthermore, intervention group subjects were more likely than control group subjects to recognize that one needs to use condoms to protect against disease, even if some other form of birth control is being used. Subjects who saw the videotape agreed more often that condom use could be "eroticized," that it is appropriate for women to insist that their lovers use condoms, and that men who refuse to us them are not thinking of their partner's well-being.

The intervention was most successful with those patients with fewer years of formal education. This finding has important clinical implications. In the various STD clinics in which we have worked, many clinicians have told us that they try harder to educate patients whom they assess to be smarter or better educated, often discounting larger numbers of patients as uneducable. The success of this intervention with those who are perceived as less educated speaks to the importance of not underestimating the potential of any patient to learn.

We feel that one of the reasons for the videotape's success was that it avoided a didactic, authoritarian tone, reflecting instead the language, beliefs, and values of the inner-city population to whom it was targeted.[35] However, just such cultural specificity is likely to render the videotape less effective with other cultural or socioeconomic groups. For example, campaigns to promote condom use among Hispanics, another high-risk group for AIDS, will have to take into account cultural discomfort with talking about sex in mixed groups of males and females and should use themes that are powerful in Latino culture, such as safeguarding fertility and protecting one's family.

Perhaps our most striking finding is the high proportion of patients from both intervention and control groups who sought free condoms by redeeming coupons. This finding strongly suggests that if STD clinics offer free condoms, they will be accepted by the vast majority of patients. Since the office where patients redeemed their coupons was immediately next door to the room where our research assistant offered the coupons, it is possible that the proximity of the two rooms, the relative ease with which coupons could be redeemed, and their packaging in unlabeled envelopes contributed to the high overall rate of redemption. Thus, while convenience factors were likely to have diminished the size of the difference between the groups, the high level of redemption in both groups speaks to the importance of engineering convenience into condom distribution programs. In addition, health educators may note that clinic redemption was much preferred to redemption by mail, a finding that seems to confirm social marketers' insistence on the importance of ease-of-purchase and accessibility to the product being promoted.[33,34]

The major limitation of this study is the difficulty in measuring changes in actual condom use: so far, researchers have been obliged to rely on self-reports and indirect proxy measures, such as coupon redemption. Methods for assessing actual condom use need to be developed and implemented.

Another limitation was our inability to track patients' knowledge and attitudes over time. Social science research points the importance of reaching the target audience repeatedly via multiple pathways.[2] As with any other one-time intervention, the effects of this videotape are unlikely to persist without reinforcement. The results of these studies suggest, however, that drama-based videotapes could be an effective component of an integrated program that continues over time.

The success with men of a videotape featuring a feminine perspective adds credibility to the observation made frequently by education intervention specialists that people are often more motivated to act out of concern for others than on their own behalf. There may be strategic advantages for condom promotion campaigns and other AIDS risk reduction efforts aimed at men to portray clearly the health risks that unprotected intercourse creates for women and children. Moreover, by portraying strong, assertive women taking responsibility for their health, educational programs have an opportunity not only to motivate men, but also to provide role models and social support to women who may wish to take more purposeful action on their own behalf. Ideally, inte-

TABLE 6—Total Number and Percentage of Coupons Redeemed by Experimental Condition

Determinants of Needle Sharing among Intravenous Drug Users

Stephen Magura, PhD, Joel I. Grossman, PhD, Douglas S. Lipton, PhD, Qudsia Siddiqi, PhD, Janet Shapiro, MA, Ira Marion, and Kenneth R. Amann, MSW

Abstract: Data from 110 IV-drug abusing persons in methadone maintenance were analyzed to determine the correlates of needle sharing. Sharing was directly related to peer group behavior, attitudes conducive to sharing, economic motivation to share, not owning injection equipment, and fatalism about developing AIDS. Sharers were aware of their AIDS risk. Indicated measures to reduce needle sharing would be positive peer support groups to help resist pressures to share, legal and free access to fresh injection equipment, education on the utility of risk reduction, and increased treatment options for IV cocaine users. (*Am J Public Health* 1989; 79:459–462.)

Introduction

Intravenous drug users (IVDUs) are the largest group at risk for the acquired immunodeficiency syndrome (AIDS) in New York City.[1,2] IVDUs also are the major window for heterosexual transmission and main source of perinatal transmission of the disease.[3] The human immunodeficiency virus (HIV) can be transmitted through contaminated blood left in needles, syringes, and other injection equipment that may be shared. Although awareness and fear of AIDS reportedly have decreased sharing of injection paraphernalia, substantial numbers of addicts still engage in such behavior.[4–6] Entry into methadone treatment has been shown to reduce IV drug use,[7,8] but some individuals nevertheless continue or revert to drug injection and non-sterile needle sharing.[9,10]

Existing research on needle sharing is quite limited. Two ethnographic studies have identified various situational factors, economic considerations, and social pressures that may lead to sharing.[11,12] A survey of drug abusers in an inpatient treatment program found no demographic or personality differences between needle sharers and other drug abusers.[5] Both the amounts of AIDS knowledge and needle sharing among IVDUs appear to be high in the New York City area,[6,13,14] suggesting that knowledge may not affect sharing.

The present study examines addicts enrolled in methadone maintenance who continue to inject drugs, comparing those who share needles and other equipment with those who do not.

Methods

The study subjects are 110 persons in methadone maintenance who volunteered for an AIDS prevention demonstration research project and who also reported current IV drug use. The subjects are a subset of a larger sample of 274 volunteers, the remainder of whom did not report current IV drug use. Subjects were drawn from three methadone clinics in New York City between January and September 1987. The project sample is 27 per cent of the total patient population, and the study subjects (IVDUs) are 40 per cent of the project sample. Because project participants were self-selected, they may not be completely representative of the patient population.

The data analyzed here were obtained from a self-administered questionnaire completed by all subjects at baseline. The questionnaire was not anonymous, but confidentiality was guaranteed; the results were not available to methadone clinic staff. Subjects were paid $15 for completing the questionnaire. The instrument consisted of fixed-response, Likert-type items written at an elementary reading level; it was also available in Spanish. Research staff were available on site to assist subjects who needed help with the questionnaires. Included were measures of knowledge about AIDS and its transmission; attitudes concerning AIDS prevention; and high-risk drug-using and sexual behaviors. IVDUs were classified as needle sharers if they reported any sharing of needles or other injection equipment within the previous month.

A set of independent variables for the analysis was derived from the questionnaire based on prior theory and research pertinent to needle-sharing behavior. These variables are: a) knowledge of AIDS risk-related behaviors; b) attitudes conducive to needle-sharing; c) intravenous drug use by one's peers; d) economic motivation to share needles; e) ownership of personal injection equipment; f) personal acquaintanceship with AIDS/ARC (AIDS-related complex) victims; g) perceived usefulness of avoiding AIDS risk behaviors; h) length of time enrolled in methadone treatment; and i) demographic characteristics. (Details of index construction are in the Appendix.)

The questionnaire also included data on needle sharers' attempts at risk-reduction, such as discretion in sharing, selectivity in partners, and equipment sterilization practices.

Results

Sociodemographic and drug use variables for the study sample are given in Table 1. Cocaine injection as well as cocaine combined with heroin ("speedballing") are predominant. The use of heroin with cocaine usually is intended to regulate cocaine effects.[15] Few subjects reported injecting heroin exclusively, thus indicating the effectiveness of methadone treatment in controlling heroin use. Methadone is not a substitute for cocaine. Forty per cent of the sample reported sharing needles or other injection equipment during the preceding month. About one-fourth of the subjects who shared needles reported doing so as part of visits to shooting gallaries; the remainder shared only in friendship networks or with sexual partners.

Table 2 presents the bivariate correlations between needle sharing and the independent variables. Some of the independent variables are also correlated among themselves (absolute mean intercorrelation = .23, range = .00 to .38). A multiple linear regression (OLS) analysis was conducted with

TABLE 1—Sociodemographic Characteristics, Drug Injection and Needle Sharing (N = 110)

Characteristics	Per Cent
Age (years)

Attitudes Conducive to Sharing	.098	(.022, .174)
Peer IV Drug Use	.093	(.010, .176)
Economic Motivation to Share	.132	(.016, .248)
Does not Own Injection Equipment	.252	(.039, .465)
Knows AIDS ARC Victims	−.030	(−.197, .137)
Perceived Utility of Risk Avoidance	.121	(.039, .204)
Intercept	−.711	

variables from Table 2, is shown in Table 3. Direct associations with needle sharing were found for attitudes conducive to sharing, peers' intravenous drug use, economic motivation to share, not owning personal injection equipment, and low perceived utility of AIDS risk avoidance. Knowledge of AIDS risks, knowing AIDS/ARC victims, gender, age, ethnicity, marital status and time in methadone treatment were not associated with sharing. Interaction effects among independent variables were not explored because of the large number of possible effects relative to the sample size.

Discussion

Apparently needle sharing cannot be attributed to ignorance about the consequences of such behavior, or how to effectively protect oneself and others against infection.

Attitudes toward sharing, however, do help explain this behavior. Addicts are more likely to share if they are unwilling to tolerate withdrawal symptoms in preference to sharing and/or if they believe that their friends would be "insulted" if they refused to share. Some can be induced to share when their friends claim that the needles are "clean." This may be due less to naivete than to reaching for an excuse to avoid threatened discomfort. Refusal to share after receiving assurances of safety may also signify distrust of one's peers.

Intravenous drug use by friends and sexual partners creates a social environment that leads to sharing. Thus our results support previous observations that peer behavior strongly influences needle sharing decisions.[11,12]

Economic pressure to share, as indicated by being unemployed and/or by a perceived inability to afford new needles, is directly associated with sharing. Limited funds often force addicts to choose between buying new injection equipment or additional drugs.

Not owning injection equipment is independently related to sharing, i.e., addicts who are reluctant to carry injection equipment, and therefore have less reason to own it, tend to rely on sharing.

The final variable identified through the regression analysis is Perceived Utility of Risk Avoidance—One interpretation of this result is that addicts with a fatalistic attitude, who believe that their past behavior has already made them highly vulnerable to developing AIDS, are prone to continuing needle sharing. An alternative interpretation is that needle sharers' fatalism is more of a reaction to their present

behavior, rather than a cause of that behavior. In that event needle sharers may simply be indicating their realistic awareness of their heightened risk for AIDS.

Needle sharers are not denying the dangers of their behavior and do report attempts to reduce the risks posed by sharing: most sharers say they have become more careful about those with whom they share needles and most claim they only borrow injection equipment in an "emergency" (Table 4). Although we cannot know how consistent or effective these risk-reduction efforts are, needle sharers are clearly aware of the implications of their conduct. Yet despite this knowledge, their desire to use a needle or to please their drug-using friends and sexual partners is strong and immediate.

Greater claimed selectivity in partners may be one reason that most needle sharers say they "never" or only "sometimes" sterilize their injection equipment after someone else uses it (Table 4). Another reason for infrequent sterilization may be that nearly half of sharers say that their friends would be "insulted if they sterilized the works" after others have used them. Finally, when injection equipment is "cleaned," it is often with ineffective sterilization techniques, e.g., water only.

The cross-sectional nature of this study makes it impossible to draw definitive conclusions about the presence or direction of causal effects. However, our statistical results are generally consistent with the findings of previous, mainly qualitative, studies. Assuming that the variables significantly associated with needle sharing in the regression model are indeed explanatory variables, some public health measures to help reduce this AIDS risk behavior can be recommended:

- One method to reduce needle-sharing would be to strengthen addicts' abilities to resist the leads of their peers, particularly (for women) of their sexual partners. What may help them are alternative sources of social support, e.g., peer groups or women's groups, where the interpersonal and communication skills necessary to resist pressures to share can be learned and reinforced.
- Free and legal access to needles and other injection equipment, not now existing in states with sizable IVDU populations, could be useful for addicts until they decide to enter treatment or begin to respond to treatment. This conclusion supports the concept of an experimental needle exchange that may soon be implemented in New York City.[17] Although this involves practical problems that are still not entirely resolved, experience with a needle exchange in Amsterdam has been favorable.[18]
- Because feelings of hopelessness or fatalism about developing AIDS may be inhibiting risk reduction, more emphasis should be placed on educating needle sharers about the potential benefits of behavioral change.
- Finally, much of the attraction of continued drug abuse among these subjects is attributable to intravenous cocaine. The data point to the need to increase community resources for preventing and treating cocaine abuse as one important weapon against the transmission of AIDS.

APPENDIX
Construction of Composite Measures

Knowledge of AIDS Risks

The correct answers were summed for 28 true-false questionnaire items (alpha = .83). Factor analysis of the knowledge item set did not reveal any separate subscales. Typical items are: "Anyone who has shot drugs might be carrying the AIDS virus now" (T); "If a needle looks clean it can't give you AIDS" (F); "You could get AIDS by having unprotected sex with a person who shot drugs" (T); and "Cleaning needles and works with soap and water will kill the AIDS virus" (F). (The full scale is available from the authors.)

Attitudes Conducive to Needle Sharing

This scale was constructed by counting responses to four items (alpha = .57): "I'd rather get sick than share works" (agree = 1); "My buddies would be insulted if I refused to share my works with them" (agree = 1); "If someone says their works are clean, I'll share" (agree = 1); and "We don't talk much about AIDS in my crowd" (agree = 1). (In the drug use context, addicts understand the term "sick" as "dope sick.")

Perceived Utility of Risk Avoidance

This scale sums responses to three items (alpha = .70): "I've already done plenty that could have exposed me to AIDS" (agree = 1); "My gut feeling is, I'm going to get AIDS sooner or later" (agree = 1); and "I never did anything that could give me AIDS" (disagree = 1).

Peer IV Drug Use

This index sums the scored responses to two items: "Some of my friends shoot up regularly" (agree = 2, not sure = 1, disagree = 0) and "In the last month, how many of your sexual partners were shooting drugs?" (two or more = 2, one = 1, none = 0).

Economic Motivation to Share

This index sums responses to two items: employment status (unemployed = 1) and "I can't afford to buy new needles all the time" (agree = 1).

ACKNOWLEDGMENTS

This work was funded by Grant No. 2 RO1 DA03281-04 (MAXIM) from the National Institute on Drug Abuse to Narcotic and Drug Research, Inc., in cooperation with the New York State Division of Substance Abuse Services. We are grateful for the support of this work given by Julio A. Martinez, Jr. (Director), Norwig Debye-Saxinger (First Deputy Director), and Charles

LaPorte (Deputy Director for Chemotherapy), all of the New York State Division of Substance Abuse Services, and by David P. Glasel (President) and John Kandall (Executive Director), both of Narcotic and Drug Research, Inc. We wish to thank the following individuals for their valuable assistance in the conduct of this study: Peter Hartsock (Project Officer); Joyce Lowinson, MD; Frederick Siegal, MD; James Koger; Kathleen Sheehan; Richard Wostek; Charles McCarrick; Lester Wesenfeld; John Langrod; Michael Rosenzweig; Steve Swain; Donald Thomas; Kevin Gehan; Theodora Owen; and Kathleen Fagan. The cooperation of all the staff and patients of the participating clinics is greatly appreciated. Reviews of the paper were provided by Don Des Jarlais, Samuel Friedman, and two anonymous reviewers. The points of view or opinions expressed herein do not necessarily reflect the official positions or policies of the sponsoring agencies.

$4.4 Million in Nursing Grants Available in Fiscal 1989

Approximately $4.4 million is available in fiscal 1989 to support new grants for nurse practitioner and nurse midwifery programs, according to an announcement in the January 6 *Federal Register*.

The grants will assist in meeting the costs of projects to plan, develop, operate, expand or maintain educational programs. It is estimated that 23 competing projects averaging $185,000 will be supported.

Public or nonprofit private schools of nursing, schools of public health, hospitals, and other public or nonprofit private entities are eligible to apply for grants, as are medical schools that received a grant or contract under section 822(a) of the Public Health Service Act prior to October 1, 1985.

Applicants that demonstrate an increase in minority enrollment which exceeds the program's prior three-year average would receive a funding priority, according to the published notice.

The deadline for applications is July 1. Application materials are available from:

Outbreaks of Hepatitis A among Illicit Drug Users, Oklahoma, 1984–87

JOHN HARKESS, MD, BARBARA GILDON, RN, AND GREGORY R. ISTRE, MD

Abstract: Transmission of hepatitis A has been described in many settings, although few outbreaks have been reported among illicit drug users. We report six unrelated outbreaks of hepatitis A among users of marijuana and intravenously administered methamphetamine. Although the exact mode of transmission could not be determined, practices associated with illicit drug use may have facilitated transmission of hepatitis A. These outbreaks and other recent information indicate that illicit drug users may be at increased risk of acquiring hepatitis A infection. (*Am J Public Health* 1989; 79: 463–466.)

Introduction

Outbreaks of hepatitis A infection have resulted from common-source food and water-borne transmission and from person to person transmission in households, day care centers, institutions for the mentally retarded, and in communities or other settings where sanitation is poor.[1–3] Although parenteral drug users are known to be at increased risk for many infections including hepatitis B, human immunodeficiency virus, and infective endocarditis,[1,4,5] they are not generally recognized to be at increased risk of hepatitis A.

Reports from Scandinavian countries have drawn attention to the occurrence of hepatitis A infections among parenteral drug abusers.[6–8] In two studies from Sweden, 42 per cent and 58 per cent of patients diagnosed with hepatitis A were found to be parenteral drug users[7,8] and prolonged outbreaks among drug users have been observed.[8,9] In the United States, 10 per cent of patients diagnosed with hepatitis A in five metropolitan counties reported using illicit drugs[10] and outbreaks of hepatitis A among illicit drug users have recently been identified in some areas.[11,12]

We report six unrelated outbreaks of hepatitis A infection that occurred among parenteral and non-parenteral drug users in Oklahoma.

Methods

A case of hepatitis A was defined as jaundice and a positive test for the IgM-specific antibody to hepatitis A virus (IgM-specific anti-HAV), or jaundice with at least two other symptoms of hepatitis (anorexia, nausea, vomiting, fever, dark urine) and no other explanation for the illness. A primary case-patient was defined as a person with hepatitis A who had not lived in the same household or had sexual contact with anyone having hepatitis A in the two to six weeks before onset of illness. A secondary case-patient was defined as a person with hepatitis A who had household or sexual contact with another person with hepatitis A in the two to six weeks before onset of illness.

Outbreaks were identified by communicable disease nurses through routine disease surveillance. In each outbreak investigation, additional hepatitis A case reports were solicited by telephone from physicians and hospital laboratories. Patients were interviewed in person about possible exposures in the two to six weeks before onset of illness including contact with any person having symptoms of hepatitis, social events attended, restaurants patronized, sources of drinking water, contact with a child in a day care center, and use of illicit drugs. For three outbreaks, age- (±5 years), sex-, and neighborhood-matched controls were identified by door-to-door survey using predetermined search patterns and interviewed in the same manner as the case-patients. Confidence intervals for odds ratios were calculated using an exact method.[13]

Results

Outbreak 1

Between October 1984 and March 1985, 13 cases of hepatitis A were reported in County A, Oklahoma compared to only a single case in the previous nine months. Investigation identified 45 persons with possible hepatitis. Illness in 29 persons met the case definition for hepatitis A: 18 persons had jaundice and a positive IgM-specific anti-HAV, and 11 persons who were not tested had illness which met the clinical case definition.

The 29 case-patients were White, ranging in age from 12–48 years (median = 24 years). 22 (76 per cent) were male. Illness onsets occurred between October 1984 and March 1985 (Figure 1A). Of the 29 case-patients, 27 (93 per cent) were fully interviewed. No common exposures to any food, eating establishment, or social gathering were identified, nor did any patients have household contact with a child attending a day care center in the two to six weeks preceding illness.

Of the 27 fully interviewed case-patients, 20 (74 per cent) had smoked marijuana and 13 (48 per cent) admitted to intravenous drug use in the two to six weeks before illness. Of the 13 IV drug users, all had injected illegally manufactured methamphetamine and eight had also injected cocaine. In contrast, of the 16 persons who were interviewed but whose illnesses did not meet the hepatitis A case definition, only one smoked marijuana during the two to six weeks before illness (odds ratio [OR] = 42.9, 95% confidence interval [CI] = 4.5-1891), and none had injected illicit drugs (95% CI lower bound = 3.24).

Of the 27 case-patients, 17 had not had household or sexual contact with a person having hepatitis A during the two to six week period preceding their illness and were classified as primary case-patients; 10 patients who had sexual or household contact with another case-patient were classified as secondary case-patients. Of the 17 primary case-patients, 15 (88 per cent) had used marijuana during the two to six weeks before illness compared to only five (50 per cent) of 10 secondary case-patients (OR = 7.5, 95% CI = 0.8-94.1). Additionally, 10 (59 per cent) of 17 primary case-patients admitted to injecting an illicit drug compared to three (30 per cent) of 10 secondary case-patients (OR = 3.3, 95% CI = 0.5-26.1).

FIGURE 1 A–C.—Hepatitis A Outbreaks among Illicit Drug Users, Cases by Week of Onset, Oklahoma, 1984–87

Matched controls were found for 12 of the 17 primary case-patients. Case-patients were similar to controls with respect to race (all White), employment (62 per cent of case-patients vs 77 per cent of controls employed), and exposure to a child in a day care center (0 vs 8 per cent); however, case-patients were less likely to be married (15 vs 77 per cent) than were controls. All 12 primary case-patients had used marijuana compared to only three of 13 (23 per cent) controls (95% CI lower bound = 2.5), and 10 of 12 primary case-patients had injected drugs compared to none of the controls (95% CI lower bound = 2.9).

Outbreak 2

Between January and March 1986, seven patients with hepatitis A were identified in County B, Oklahoma (Figure 1B). No cases had been reported in that county for the previous six months. The patients ranged in age from 19 to 33 years (median = 26.5), five (71 per cent) were male, and all were White. Six (86 per cent) patients had a positive IgM-specific anti-HAV; one refused phlebotomy.

On investigation, no common social gathering or eating establishment was identified, and no case-patient had had household contact with a child in a day care center. One patient who had been a household contact of a jaundiced person during his exposure period was classified as a secondary case. None of the sexual or household contacts identified by the remaining six case-patients were known to have had clinical hepatitis during the patient's exposure period.

All six primary case-patients had used an illicit drug during their incubation periods; five regularly smoked marijuana and five had intravenously injected methamphetamine. For three case-patients, methamphetamine had been prepared and injected for them by someone who was ill with hepatitis A during the two to six weeks before illness. A fourth patient had shared a marijuana cigarette with a jaundiced person in the two to six weeks before his onset.

Two matched controls each were found for five of the six primary case-patients. Four (80 per cent) of five primary case-patients had smoked marijuana compared to two (20 per cent) of 10 controls (OR = 7.0, 95% CI = 0.6, 334), and four (80 per cent) primary case-patients had injected drugs compared to none of the controls (95% CI lower bound = 1.8).

Outbreak 3

Between June 1 and August 29, 1986, 12 persons became ill with hepatitis A in County C, Oklahoma (Figure 1C) compared to only four cases reported during the preceding 17 months. One patient was 3 years old, the remainder ranged in age from 14 to 27 years (median = 23). Eight (67 per cent) were male, and all were White. Eleven (92 per cent) patients had a positive IgM-specific anti-HAV; one refused phlebotomy.

No common exposure to an eating establishment, social gathering, or day care center could be identified. Of the 12 case-patients, 11 (92 per cent) were classified as primary case-patients and one was classified as a secondary case-patient. None of the eight sexual contacts identified by seven of the 11 primary case-patients were homosexual men and none had clinical hepatitis in the preceding months.

Of the 11 primary case-patients, eight (73 per cent) had smoked marijuana, two (18 per cent) had consumed raw hallucinogen-containing mushrooms, and four (36 per cent) had injected illegally made methamphetamine during the two to six weeks before illness. Matched controls were found for 10 of the 11 primary case-patients; no control was sought for the 3-year-old case-patient. Of the 10 primary case-patients, eight (80 per cent) had used an illicit drug during the two to six week incubation period compared to none of the control patients (95% CI lower bound = 2.2). Additionally, three case-patients had interacted with someone who had hepatitis during the two to six weeks before onset of illness, but in all three cases the contact did not include sex, consumption of food prepared by the ill person, or living in the same household. One case-patient had consumed raw hallucinogen-containing mushrooms that were purchased from another ill case-patient, one patient had shared a marijuana cigarette while visiting with another ill case-patient, and one patient had shared a marijuana cigarette and intravenously injected amphetamines purchased from another ill case-patient.

Outbreaks 4–6

Three additional outbreaks of hepatitis A among illicit drug users have been investigated in Oklahoma since 1984. Nine cases occurred in County D from September to December 1985 (Figure 1D), six cases in Town E from November 1986 to March 1987 (Figure 1E), and 10 cases in County F from October to December 1987 (Figure 1F). As in the outbreaks already described, most cases occurred among young adults males over a period of two to five months (Table 1). In five of the six outbreaks, one or more of the case-patients was identified as a dealer or distributor of illicit drugs. In all five instances, cases among dealers occurred early in the outbreak and before illnesses in persons known to have been customers (Figures 1A–F).

TABLE 1—Summary Data for Six Unrelated Outbreaks of Hepatitis A among Illicit Drug Users, Oklahoma, 1984–87

Location	Duration (months)	Total Cases	Age Range (years)	% 15–25 Years of Age	% Males	Smoked Marijuana			Injected Drugs			Used Any Illicit Drug

Discussion

In the hepatitis A outbreaks reported here, illness occurred almost exclusively among young adult men, most of whom had used illicit drugs during their time of likely infection with hepatitis A virus. No evidence of common-source transmission was found, and most patients had not had close personal contact with another person with hepatitis. Findings which suggested that drug use practices may have played a role in transmission of these infections include:

- In Outbreak 1, marijuana and parenteral drug use was more common among case-patients than among persons whose illnesses did not meet the case definition;
- In Outbreak 1, illicit drug use was more common among primary case-patients whose source of infection was uncertain than among secondary case-patients whose likely sources of infection were apparent;
- Primary case-patients in three outbreaks were more likely than matched neighborhood controls to have used illicit drugs;
- the most likely sources of infection for seven patients in Outbreaks 2 and 3 were other ill persons who had sold, shared, handled, or prepared and injected drugs for them. As best we could determine, other contact between these persons was casual and did not involve sexual contact, living in the same household, or the consumption of food prepared by the ill person.
- Illnesses among drug dealers, who handled, sold, and helped others to inject drugs, occurred early in the outbreaks and preceded illnesses among known customers.

Poor personal hygiene and inferior living conditions which may accompany illicit drug use have been advanced as possible explanations for hepatitis A outbreaks among drug users in Scandinavia.[6] However, it is possible that drugs and associated apparatus may be vehicles for transmission of hepatitis A. The conditions under which illicit drugs are produced, transported, mixed with other substances, and prepared for use may allow fecal contamination to occur. Fecal contamination of rectally carried drugs was thought to have been responsible for one outbreak of hepatitis A among intravenous drug users in Sweden.[9] In the outbreaks reported here, persons ill with hepatitis A may have fecally contaminated spoons, cotton filters, or the drug itself while preparing and intravenously administering it to persons who subsequently became ill. Transmission of hepatitis A by blood transfusion has occurred[14,15] so parenteral transmission through the use of contaminated needles may also be possible.

Some case-patients admitted only to having smoked marijuana. Patients we interviewed described frequently handling marijuana while rolling cigarettes and occasionally swallowing small particles left in their mouths after inhaling from hand-rolled cigarettes. Contamination of marijuana with fecal coliforms was demonstrated in samples obtained during an outbreak of hepatitis A among drug users in Alaska,[11] and smoking or handling of fecally contaminated marijuana has been implicated in the transmission of salmonellosis.[16] Since

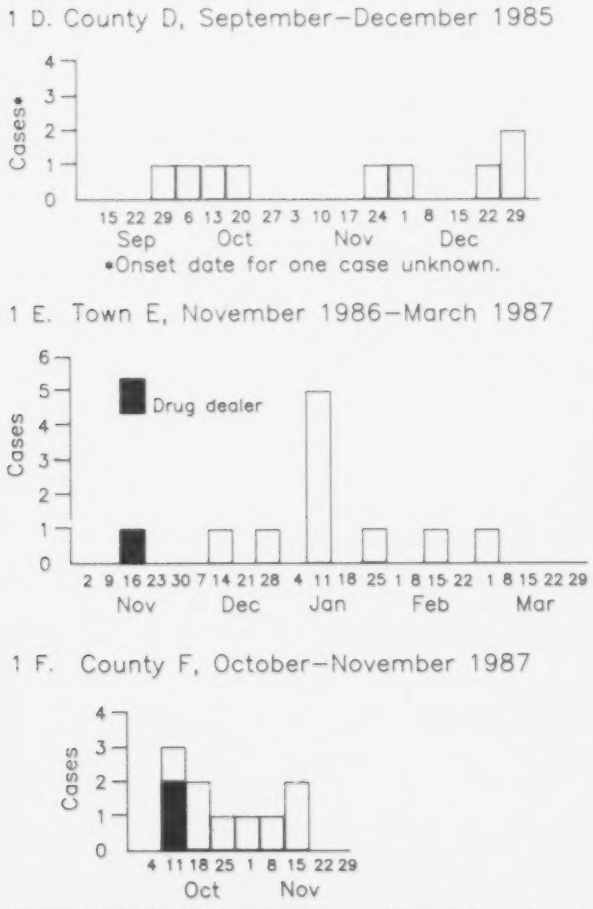

FIGURE 2 D–F—Hepatitis A Outbreaks among Illicit Drug Users, Cases by Week of Onset, Oklahoma, 1985–87

hepatitis A virus has been shown to survive as long as a month in dried feces,[17] it is possible that fecally contaminated marijuana could be a vehicle for hepatitis A.

The small number of cases that occurred in these outbreaks and the difficulties in obtaining accurate information from patients regarding the use and origin of illicit drugs make it difficult to determine the exact mode of transmission. With the imminent development of a vaccine for hepatitis A,[18] the identification of illicit drug users as being at increased risk of infection may have implications for prevention.

New AIDS Prevention Research Center to be Established at Columbia University

Columbia University is creating a $3.6 million center in its School of Social Work that will study and help apply measures to prevent the spread of AIDS among young people in minority groups. The new AIDS Prevention Research Center will develop and implement a variety of community-based techniques in the New York area to prevent the spread of AIDS among minority youths through the reduction of intravenous drug use and unsafe sexual behavior. The center will focus its efforts in Harlem and Northern Manhattan.

Minority youths are being targeted because the incidence of AIDS among minority groups is disproportionately high; Blacks and Hispanics accounted for 40 per cent of AIDS cases nationwide as of October.

The center will be supported by a five-year, $3.6 million grant from the National Institute on Drug Abuse, obtained with the support of Rep. Charles B. Rangel of New York.

Program participants, 8 to 16 years old, will be taught how to use problem-solving skills and to develop alternatives to high-risk activities. Assertiveness training, avoiding drug use, and learning safe sexual practices will be covered. Participants will not be tested for AIDS. Through personal and computer instruction, they will be taught ways to avoid exposure to AIDS. Information will be tailored to the youths' particular neighborhoods.

In supporting the center, Rep. Rangel said, "The survival of the minority community is dependent upon our arresting the AIDS epidemic, which means stopping the drug abuse that is responsible for so many of these cases. The new AIDS Prevention Research Center provides the opportunity for scientists and researchers to become intimately involved with the communities most devastated by the AIDS epidemic and equip members of those communities with the skills necessary so that they, themselves, can continue to fight this epidemic in the months and years to come."

Race and the Prevalence of Syphilis Seroreactivity in the United States Population: A National Sero-Epidemiologic Study

ROBERT A. HAHN, PHD, MPH, LAURENCE S. MAGDER, MPH, SEVGI O. ARAL, PHD, ROBERT E. JOHNSON, MD, MPH, AND SANDRA A. LARSEN, PHD

Abstract: We used the 1978 National Health and Nutrition Examination Survey to examine the prevalence of positive syphilis serologies in the US population. Analysis of risk markers—gender, age, marital status, education, income, and residence—indicates that all except gender are associated with syphilis seroreactivity, independent of race. Controlling for associated risk markers, the Black-White odds ratio of syphilis seroreactivity is 4.7 (95% CI=2.7, 8.2). Current knowledge of racial differences in sexual and health care behavior does not explain the Black-White difference in the prevalence of syphilis seroreactivity. (*Am J Public Health* 1989; 79:467–470.)

Introduction

During the past 50 years, surveys with varying design have reported large racial differences in the incidence and prevalence of syphilis seroreactivity in the United States.[1–6] Among four million young male military recruits in the 1940s, syphilis rates were more than 13 times higher in Blacks than in Whites[1,2]; in community studies in Baltimore in 1939[4] and Savannah in 1945,[5] Black males were seroreactive at rates 9 to 16 times the rates for White males, and Black females between 16 and 21 times those of White females. Similarly, the first US population-based National Health Examination Survey (NHES-I) in 1960–62 found evidence of syphilis seroreactivity in 10 times as many Black as White men, and in eight times as many Black as White women.[6] Finally, a study of reported primary and secondary syphilis in New York State (outside of New York City) between 1975 and 1981 indicated a Black-White ratio of 8.4.[6]

To reduce the excess risk of syphilis among Blacks, and to control the incidence of syphilis in the general public, we must know not only the distribution of risk in the population, but also those aspects of the social environment which are related to incidence and which may be altered to reduce it. However, with the exception of NHES-I,[6] previous epidemiological analyses of racial differences[2–4] have been limited by sample selection and size, or by restriction to a small segment of the US population.

To further explore these relationships, we examined the distribution of positive syphilis serology in the US by analysis of the second (1978) National Health and Nutrition Examination Survey (NHANES-II)—the largest population-based health examination survey of the US conducted to date.[7] We tested the hypothesis that racial differences in syphilis seroreactivity are explained by differences in the distribution of sociodemographic risk markers—gender, age, marital status, residence, income, and education.

Mr. Magder is a statistician currently attending Johns Hopkins University. Dr. Aral is a sociologist-demographer, and Dr. Johnson is a medical epidemiologist, all with the STD Division, CPS, CDC. Dr. Larsen is Chief, Treponema Research Branch, STD Laboratory Program, CID, CDC. This paper, submitted to the Journal June 13, 1988, was revised and accepted for publication October 4, 1988.

Methods

Between 1976 and 1980, the National Center for Health Statistics conducted a stratified probability cluster survey of the US population, NHANES-II.[7] Of 27,801 civilian, noninstitutionalized individuals selected, 20,243 were Whites and Blacks 12 years of age and older. In this study we considered only Blacks and Whites age 12 and older. Of these, 18,094 (89 per cent) completed the interview regarding demographics and health and nutritional status; 14,196 subjects (70 per cent of those selected) were administered physical and laboratory examinations. The interview did not include questions on sexual history or history of sexually transmitted diseases (STD); the physical examination did not include the genitalia. Sera sufficient for syphilis testing were available from 12,989 subjects, 92 per cent of those examined. Tests for syphilis seroreactivity were conducted by the Sexually Transmitted Disease Laboratory Program at the Centers for Disease Control.

Sera were screened with the Automated Reagin Test (ART) and quantified with the Rapid Plasma Reagin Test (RPR). Sera reactive in the screening test were confirmed with subsequent reactive results on either the Microhemagglutination Assay for Treponema Pallidum (MHA-TP) or the Fluorescent Treponemal Antibody Absorption Test (FTA-ABS).[8,9]

Projections of US population characteristics based on the NHANES-II sample examined are generally comparable to projections based on the total sample.[10] Similarly, comparison of projected population characteristics from the NHANES-II sample interviewed but not tested for syphilis with projections from the sample tested suggests no major bias in study estimates based on the sample tested (see Appendix).

In our estimation of prevalences and odds ratios of seroreactivity, each subject was assigned a weight based on three characteristics: the probability of being sampled by NHANES-II, refusal to be examined (adjusted for age, income, urban residence, and region), and a poststratification factor to ensure that the weighted sample agreed with that of the US population in mid-1978 in distributions of gender, race, and age. Standard errors of prevalence and odds ratio estimates were made with a first order Taylor series approximation, incorporating the complex sample design.[11,12]

Several sociodemographic risk markers are associated with race in the NHANES-II population. Blacks are younger and less likely to be married; they live more commonly in central cities, have less education and lower incomes. These sociodemographic risk markers might confound the association of race and syphilis seroreactivity.

We estimated odds ratios for each sociodemographic risk marker (i.e., race, gender, age, income, etc.) while controlling for other factors, using logistic regression.[11] Because eventual education and marital status are less likely to be established by age 20, we restricted these analyses to subjects age 20 years and older. We also ascertained odds ratios for Blacks versus Whites in substrata defined simultaneously by education, income, and marital status, for which the sample was large enough ($n \geq 50$ for each race) for reasonable estimation.

Results

The prevalence of syphilis seroreactivity among persons 12 years of age and older in the 1978 US population is estimated to be 0.81 per cent (Table 1). The prevalence among Blacks is 3.05 per cent and among Whites it is 0.53 per cent, for a crude prevalence ratio of 5.7 (95% CI = 3.8, 8.6).

As expected, the prevalence of seroreactivity is related to age, marital status, residence, income, and education; prevalence is little affected by gender (Table 1). For the most part, the associations of these sociodemographic risk markers and syphilis seroreactivity hold both for the population as a whole and for the population stratified by race (Table 1). Prevalences for seroreactivity in Blacks relative to Whites are substantially elevated in all sociodemographic strata, except for those with income greater than $15,000.

The odds ratio of positive serologies, Blacks versus Whites, is 4.7 (95% CI = 2.7, 8.2) when the effects of other variables are controlled by logistic regression (Table 2). There is no statistically significant interaction between race and any of the variables for which we controlled. Prevalence of seroreactivity increases with age, and decreases with college education and greater income. The higher prevalences of seroreactivity among non-married persons and persons living in large cities (SMSAs) are reduced substantially after controlling for other risk markers. The independence of the association between race and seroreactivity is further supported by stratified analysis (data available on request to author).

TABLE 2—Odds Ratios of Syphilis Seroreactivity for Each Sociodemographic Risk Marker, Independent of all Others

Risk Marker	Odds Ratio (95% CI)
Race (Black vs White)	4.74 (2.74–8.20)
Age (per year)	1.05 (1.04–1.06)
Income (per $5,000 decrement)	1.30 (1.01–1.67)
Education	
No High School (HS) vs HS	1.14 (0.62–2.09)
HS vs some college	2.48 (1.07–5.76)
Residence (large city vs not)	1.30 (0.77–2.19)
Marital Status (not married vs married)	1.47 (0.82–2.66)
Sex (male vs female)	1.27 (0.77–2.10)

Discussion

We found Black race to be a strong risk marker of syphilis seroreactivity in the US population, independent of other standard sociodemographic risk markers, a finding consistent with earlier studies. While previous studies have used different serological tests and test sequences, our findings, along with another recent investigation,[6] indicate that the race differential may be narrowing. The crude prevalence ratios of syphilis for Blacks versus Whites appear to have declined from between 9 and 21 in the 1940s, to 8–10 in the 1960s, to 5–8 in the late 1970s. Nevertheless, a large and significant racial difference persists.

Because the syphilis tests used in NHANES-II may become nonreactive after longstanding infection, with or without treatment,[13] or after treatment of early syphilis,[14] this sequence provides a conservative estimate of prior

TABLE 1—Prevalence of Syphilis Seroreactivity in NHANES-II: Per Cent Seropositive (± 1.96 se)

infection. The test sequence also introduces a possible bias in the comparison of race-specific seroreactivity. If Blacks receive medical treatment less frequently, or delay more often than Whites in seeking treatment, they would be more likely than Whites to be detected by the NHANES-II test sequence, given infection. Such ascertainment bias would artificially raise the odds ratios of Blacks over Whites.

Black-White differences in syphilis seroreactivity might be mediated by increased susceptibility to infection among Blacks, given the same exposure, or by greater capacity to sustain or transmit infection. However, while Blacks and Whites are reported to manifest differing symptoms in later stages of syphilis,[15] no studies have demonstrated either differential susceptibility to infection or differential capacity to transmit. Studies which purport to show racial differences in the likelihood of disease transmission per sexual contact[16] have not assured comparable exposures among Black and White subjects.

Higher rates among Blacks than among Whites have been found for a variety of sexually transmitted diseases. Reported gonorrhea is 10 times higher in Blacks in the US population[17*] and between 4.5 and 10.7 higher among women of reproductive ages, adjusted for several measures of sexual activity.[18] Black women in the US population report 1.8 times the rate of ambulatory or hospitalized treatment for pelvic inflammatory disease (PID) as do Whites,[19] and observed hospitalization for PID is 2.5 times more common in Blacks than in Whites.[20] Rates of infertility are 1.9 times greater in Blacks than in Whites.[21] Herpes simplex virus type 2 antibody, controlling for gender, is 3.4 times higher in Blacks,[**] while hepatitis B antibody, controlling for a variety of sociodemographic risk markers, is 4.6 times higher in Blacks.[†] AIDS has affected Blacks at a rate 3.1 times that for Whites.[22] Cervical cancer, suspected of an STD etiology,[23] is 2.3 times more common in Blacks.[24]

Population-based surveys of the US[25] have not yet provided comprehensive information on sexual behavior or racial differences in sexual behavior. The most current information compares White and Black women of reproductive age in Los Angeles[‡] and in the US population.[26] Several reported characteristics of Black women place them at greater risk of STD. The initiate sexual activity earlier and are more sexually active until age 25, when this difference diminishes[26,‡]; they use barrier methods of contraception less frequently than Whites.[‡] Both Black and White women prefer same ethnicity sexual partners[‡]; thus Blacks are more likely than Whites to have sex in a high prevalence population.

In contrast, other characteristics place Whites at greater risk of STD. Whites report greater numbers of sexual partners than Blacks,[‡] and more frequent sexual activity.[‡,26] From these initial current findings, the overall picture of (female) Black-White differences in sexual behavior does not clearly put either group at higher risk.

Evidence on racial differences in treatment for syphilis, other STDs, and other health problems is also sketchy and inconsistent. With regard to health care in general, Blacks are far less likely to be covered by private or federal health insurance[27]; in both good and poor health, Blacks have consistently fewer physician contacts per year.[28] With regard to treatment for STDs, in Columbus, Ohio, fewer White than Black heterosexual patients reported curtailing their sexual activity when they perceive dysuria or urinary tract discharge; patients' response to symptoms of syphilis were not elicited in this study.[29] Whites also delay clinic visits between 30 per cent and 90 per cent longer than Blacks with similar symptoms.[29] It is unclear how findings on health care seeking in general or of sexually transmitted disease clinic patients with discharge or dysuria might apply to patients from the general population with syphilis infection.

Race specific differences may be explained in part by historical differences in prevalence and by the predominance of intraracial sexual relations. While the present study demonstrates the significantly greater prevalence of syphilis seroreactivity among Blacks than among Whites, we do not yet know enough about racial differences in sexual behavior through which infection is acquired, or about racial differences in ways in which infection is eliminated to explain persisting differences in prevalence.

New Name: Advisory Council on Nurses Education

A name change—from the former National Advisory Council on Nurse Training—and a new charter were announced recently by HRSA. Now known as the Advisory Council on Nurses Education, the council will be increased in size from 19 to 21 members appointed by the Secretary of Health and Human Services. The changes implement provisions of the Nursing Shortage Reduction and Education Act of 1988.

The nursing council will continue to advise and make recommendations to the HHS Secretary and the HRSA Administrator on regulations and policy matters arising from the administration of nurse training programs, and review grant applications and make recommendations for various nurse education programs authorized under Title VIII of the Public Health Service Act.

For further information, contact Blake Crawford at HRSA, PHS, USDHHS, 5600 Fishers Lane, Rockville, MD 20857. Tel: (301) 443-3376.

Mumps in the US Army 1980–86: Should Recruits Be Immunized?

David R. Arday, MD, MPH, Devesh D. Kanjarpane, MD, and Patrick W. Kelley, MD, MPH

Abstract: The US Army's experience with mumps hospitalizations was examined for the years 1980 through 1986. One hundred fifty-two cases among active duty Army soldiers were identified. Mumps rates declined from 3.85 per 100,000 active duty soldiers per year in 1980 to 1.28 in 1985, but an outbreak during 1986 caused rates to jump to 6.65. Attack rates were found to decline dramatically with increasing age or length of military service, with 74 per cent of cases occurring in soldiers with three years or less of service. Rates for Blacks and Whites were similar, but were higher for other minorities. Complications reported were mild. A cost-benefit analysis, assuming all recruits were to be vaccinated, estimated average annual vaccination program costs of $286,789; this figure exceeds average annual reported hospitalized mumps disease costs of $61,525 by a factor of 4.7. Mumps attack rates would have to reach at least 15.0 per 100,000 per year before savings would equal recruit vaccination costs. Failure to show that a vaccine program would be cost-saving may be due to limitations in identifying cases or to the requirement that all recruits be immunized regardless of prior immune status. It is likely that a program to immunize susceptible individuals alone would show benefit. (*Am J Public Health* 1989; 79:471–474.)

Introduction

Mumps has been perceived as an acute communicable disease of childhood for at least 20 years, but in earlier times it was viewed primarily as an illness that affected armies during mobilizations. Mumps was one of the most important causes of days lost from active duty by the US Army in France during World War I, with an average annual hospitalization rate of 55.8 per 1,000 average strength.[1] In World War II and afterward, however, the US military experienced much lower mumps rates and only isolated epidemics. This decrease between the world wars was attributed to increasing urbanization with resulting increased transmission during childhood.[2]

The introduction of mumps vaccine in December 1967 resulted in a dramatic decline in reported mumps attack rates among the US population. Centers for Disease Control (CDC) figures show a 98 per cent drop from 1968 levels, to an all-time low of 1.2 cases per 100,000 population in 1985.[3] In 1986 and 1987, however, there were reports of mumps outbreaks in secondary schools and colleges.[4,5] US rates rose to 3.2 per 100,000 in 1986, with 7,790 cases reported, while the provisional total for 1987 is even greater at 12,200 cases.[5] These increases have resulted in calls for vaccination programs directed at young adults who have not been immunized previously.[4,6]

The US Army, whose soldiers are largely in their early 20s, experienced a similar mumps outbreak in a unit stationed in the Republic of Korea during the spring of 1986. This outbreak consisted of 29 known symptomatic cases over a four-month period, with a crude attack rate of roughly 4 per 1,000 soldiers. (CPT Robert Pero, MD, unpublished data.) In response to this outbreak and the perception that a new immunization program for recruits might be indicated, this study was undertaken to examine the recent history of mumps in the US Army, and to consider whether an immunization program would be justified on cost grounds.

Methods

The US Army Medical Department maintains a worldwide, computerized Individual Patient Data System (IPDS) hospital admission data base for administrative purposes. Each IPDS hospital discharge record contains basic demographic, geographic, length-of-stay, and disposition information, including convalescent time, as well as up to eight diagnoses and eight procedures. These are coded according to the International Classification of Diseases, 9th Revision (ICD-9).

All discharge records with a mumps-related ICD-9 code for the years 1980–86 were retrieved. This period was chosen because it was felt that policy should be based on the Army's most recent experience with mumps illness for which accurate data are available. Because the question of interest is mumps disease impact on active duty soldiers, the 215 total cases identified were limited to a subset of 152 active duty Army, excluding dependents, retirees, and other service members. Denominator data were obtained from the Defense Almanac, published annually by the Department of Defense.

While mumps in the civilian population may be underreported by as much as a factor of 10,[7] military symptomatic cases have a much higher reported hospitalization rate, especially among lower ranking soldiers who live in barracks. These individuals are admitted to respiratory disease wards largely as a transmission control measure, e.g., virtually every overtly symptomatic case in the Korean outbreak was hospitalized. Hospitalized cases were therefore used as a proxy for all cases, with the understanding that some underestimation remains.

Outpatient costs associated with mumps hospitalization were calculated assuming two clinic visits per case (admitting and follow-up) plus one additional follow-up visit for each complication reported during hospitalization. Clinic and daily hospitalization costs for the most recent (1986) fiscal year were obtained from the Army Health Services Command (HSC) which calculates average costs across all Army hospitals within the 50 states. These costs are $322.82 and $67.83, respectively, and include all associated plant, salary, supply, and inpatient medication expenses. Overseas costs in US Army facilities are similar, due to use of similar staffing and military supplies.

As the analysis used is based on a steady state model in the present, the 1986 costs were applied to all cases, ignoring inflation during the period. Intangible costs for pain and suffering were excluded. Average annual costs were computed using the mean annual number of hospital days and convalescent days (to estimate total lost pay costs) for the entire seven years of data, and these average costs were

From the Department of Advanced Preventive Medicine Studies, Division of Preventive Medicine, Walter Reed Army Institute of Research, Washington, DC 20307. Address reprint requests to Dr. Patrick W. Kelley at that address. This paper, submitted to the Journal April 26, 1988, was revised and accepted for publication August 19, 1988.

compared with average annual estimated vaccine program costs.

The Army currently administers measles and rubella vaccine (MR) to all enlisted recruits. Therefore the cost to initiate a mumps vaccination program would be little more than the Army's additional cost per dose for measles, mumps and rubella vaccine (MMR) over MR. In mid-1987, this cost was $1.542, based on the standard 10-dose vials. The estimation of mumps vaccine administration costs was derived by applying this incremental cost to the 180,000 average annual number of enlisted accessions to basic training (MAJ John Brundage, MD, MPH, personal communication), a number which includes Army Reserve and National Guard enlistees.

An 85 per cent overall vaccine effectiveness rate was assumed in calculating disease costs that would accrue in spite of a vaccination program. Recent estimates of clinical mumps vaccine efficacy range from 75–91 per cent.[5,8,9] Officer accessions, however, as well as all current active duty would not be included in the proposed program, so overall effectiveness in this population would tend to be less than the maximal efficacy. (In the earliest years of such a program, effectiveness might be lower still, since only new accessions would be covered.)

Results

Table 1 summarizes the active duty experience of mumps hospitalizations over the seven-year period. While grouped age-specific rates are included for comparison, the Army's age distribution is very skewed to younger ages in the groupings above age 20, causing some of the apparent elevation of these rates. The direct age-adjusted Army rates are below reported US rates for the same period. Prior to 1986, rates had been trending downward for both the Army and the US, but the Korean mumps outbreak caused the Army rates to increase five-fold that year as compared to 1985. Through December of 1987, the Army recorded 33 active duty cases, making the provisional 1987 rate 4.2 per 100,000. This is a decline from 1986 rates, yet is still twice the 1980–85 average of 2.14.

TABLE 1—Annual Incidence of Mumps Hospitalizations per 100,000 Active Duty US Army Soldiers for the Years 1980–86 Compared with Overall US Mumps Rates as Reported by the CDC*

*US rates for 1980–83 derived from MMWR's Annual Summary, 1980 through 1983, published by CDC; other US rates from reference 5. DOD and CDC use different age groupings in compiling their published data.

†Direct adjustment to resident US population distribution per Statistical Abstract of the United States, published annually by US Bureau of the Census.

Age, race, sex, and length of service-specific rates for the entire period are presented in Table 2. There is a clearly decreasing trend in attack rates with respect to age and length of service. While rates for Blacks and Whites appear similar, those for other minorities are significantly higher. In 1985, the Army began classifying Hispanics as a distinct race/ethnic category in IPDS data. Race/ethnic rates were recalculated for 1986 alone, with the Hispanic rate, based on five cases, being more than twice that of Whites. No overall difference with respect to sex was found.

Clearly, the sharp decline in rates with increasing length of service is confounded by the fact that those with longer service records are usually older. However, mumps is not occurring primarily in basic training camps. Only 15 (9.9 per cent) of the cases occurred in soldiers within their first 90 days of service.

It was considered that because of much higher rates 1986 might have been different from the 1980–85 period, so the analysis was repeated for these years separately. Except for the higher rates, the mumps disease patterns in 1986 were consistent with the prior years, and it is therefore appropriate to use all seven years of data for the overall cost-benefit calculations.

Complication rates are important in estimating permanent sequelae and total disease costs. Unfortunately, the ICD-9 does not list all possible mumps complications in its coding system (e.g., mastitis, reported in 15 per cent of females[10]) so it cannot be determined if these occurred. Seventy-nine per cent of the cases had no reported complications. Among mumps-related complications, orchitis was seen most frequently (26 cases, 19 per cent of males), followed by meningitis (two cases) and encephalitis, nephritis, and testicular atrophy (one each). These complications were apparently mild, and all 152 patients returned to active duty without disability.

The median number of sick days (inpatient plus conva-

lescent time) was seven, and the mean 9.6. Inpatient care amounted to 73 per cent of total sick time, with the remainder spent on convalescent leave. The range in total sick time was 1 to 267 days, with 95 per cent of the patients having 19 or fewer days. The most extreme outlier suffered complications due to gastric surgery. Another outlier at 49 days suffered complications of labor and delivery. Since it was not known whether these complications were not in some way related to the individuals' mumps illnesses, they were retained in the cost calculations with the understanding that any resulting bias would tend to favor a decision to immunize.

Estimated annual disease costs were calculated based on the mean attack rate for the 1980–86 period. There were a total of 1,057 inpatient hospital days recorded, an average of 151 per year. Multiplying by the specified daily hospital cost yields an average annual hospitalization cost of $48,764. The estimated total number of associated clinic visits was 207, or 30 per year. Multiplying by the specified clinic visit cost yields an average annual clinic cost of $2,006. Lost pay costs based on total reported sick days and pay scales in effect on January 1, 1987 were $75,412, an annual average of $10,773. The sum of these three average annual costs is the total estimated disease cost for an average year at 1986 cost levels, $61,525.

Estimated vaccine program costs (annual number of enlisted accessions multiplied by the $1,542) yielded a figure of $277,560. Applying the estimated 85 per cent vaccine effectiveness rate to the average number of reported cases left an expected three nonpreventable cases. Costs for these cases were calculated proportionally to be $9,229. Thus, the total estimated annual expenses under a vaccination program would be $286,789. This exceeds the direct and indirect costs for hospitalized cases by a factor of 4.7.

Table 3 compares disease costs with vaccination program costs at various attack rates assuming a steady state. The costs for 1986 were calculated from that year's data alone by the same procedure as the overall comparison described above. It is worth noting, however, that the extrapolated estimate of total 1986 disease costs, using the overall average cost per case, would be within $2,500 (1.6 per cent) of the actual cost. This agreement tends to support the extrapolation to the break-even number of cases and corresponding attack rate, which were solved for algebraically under the assumption that all disease costs would rise proportionately with increasing rates.* Reported mumps attack rates would have to exceed at least 15.0 per 100,000 annually before the cost ratio would favor vaccination.

TABLE 3—Comparison of Hospitalized Disease vs Vaccination Program Costs at Various Mumps Attack Rates

	Average 1980–86	1986	Break-even*
Attack rate (per 10^5 per year)	2.78	6.65	15.0
Number of cases	22	52	117
Mumps disease cost			
Medical costs	$50,752	$126,240	$269,350
Nonmedical costs	10,773	16,977	57,200
Total	$61,525	$143,117	$326,550
Vaccination program costs			
Vaccine cost	$277,560	$277,560	$277,560
Non-preventable case costs	9,229	21,468	48,990
Total	$286,789	$299,028	$326,550
Vaccine:mumps cost ratio	4.7	2.1	1.0

*Projected costs and rate at break-even point are rounded estimates.

Discussion

The use of hospitalization records to estimate rates and compute costs is not without pitfalls, but some of these may be minimized by the unique aspects of the military population under study. Because of the much higher hospitalization rates for mumps in the military, these rates are felt to be an adequate proxy for reported rates. However, there are still limitations in identifying cases. Asymptomatic cases are almost never reported in either the civilian or the military sector, but from a cost-benefit standpoint, asymptomatic cases do not contribute any costs, and their exclusion is less important. Mild cases, which are unhospitalized and undocumented, would incur medical and nonmedical costs, but at a lower rate.

The racial differences noted may be of some interest, especially the apparently high non-Black minority rate. Previous studies have tended to show that race has no effect, although Blacks may have higher rates at an earlier age.[11] Our data are insufficient to determine if these higher rates are limited to Hispanics alone. A similar data analysis showed that in 1985 Hispanics in the Army had roughly six times the rate of varicella illness, relative to Whites (MAJ Patrick Kelley, MD, MPH, unpublished data). Many of these cases came from Puerto Rico where varicella transmission is low. It is speculated that either a similar difference in prior exposure or a difference in prior immunization is occurring with Hispanic mumps cases.

As any mumps-related diagnosis caused inclusion in the data set, it was impossible to determine if a complicated case acquired the infection before or after admission, and thus whether the reported complications were directly related to the mumps infection. The decision to include the outlying cases in the cost calculations increased the estimated disease costs by roughly 20 per cent. On the other hand, the fact that the IPDS data did not differentiate intensive care unit (ICU) bed days from regular bed days might lead costs to be underestimated (the Army's medical ICU bed cost is nearly three times higher than regular bed cost), although medical ICU usage in mumps illness is probably limited to the rare severe meningitis or encephalitis case.

Including Army Reserve and National Guard trainees in the proposed immunization program increases program costs, while most disease prevention savings would occur outside the military health care system where it is not captured in the calculations. These recruits train side-by-side with active duty soldiers and are required to receive the same vaccinations, but return to civilian life within 120 to 180 days. About one-third of the basic trainees are reservists or guardsmen during a given year. Assuming their disease rates are the same as the active duty population, the total mumps disease cost might be one-third higher. This is still not enough for the program to be cost-beneficial.

The conclusion that the proposed vaccination program might not save money was not expected. There is no doubt

*The equation solved is (cost per case) x = (vaccine cost) + (proportional cost for non-preventable cases), where x is the number of mumps cases at which vaccination program costs equal disease costs, and the proportional cost for non-preventable cases is 0.15 (cost per case) x. This is a linear extrapolation based on the average cost per case.

that vaccination programs are cost beneficial when applied to completely unvaccinated populations.[12,13] What is certainly the case here, however, is that a large proportion of the military recruit population is already immune, due to prior vaccination or illness. Surveys of US military recruits taken in the 1950s and 1960s, when post induction mumps rates were higher, found antibodies to be present in 54–76 per cent.[14,15] Cochi, *et al.* using data from the United States Immunization Survey, estimate vaccine coverage in 15–19 year-olds at 55 per cent and rising, as of 1985.[5] This immunity has two major impacts on the results. First, it prevents attack rates from approaching those seen in pediatric or otherwise virgin populations, on which most previous cost-benefit analyses were based. Second, it means that a large amount of the vaccine given in a blanket immunization program would be wasted, raising vaccination costs unnecessarily.

The Army does not generally use previous civilian immunization records to exempt basic trainees from the usual schedule of vaccines, so the obvious solution of simply vaccinating those without proof of prior immunization could not be immediately implemented. Relatively few recruits now arrive at basic training camps with valid immunization records in hand, and the administrative costs of determining each individual's immune status may exceed the $1.54 vaccine cost. As preinduction immunization rates for mumps and other diseases rise, however, a policy of selectively immunizing recruits based on review of records would likely become cost-beneficial.

Excluding intangible costs for pain and suffering, as well as neglecting later life costs of sequelae, may be questioned in this study because of the failure to show any strict monetary benefit from a vaccine program. In fact, if the cost ratio had been closer to 1.0 we would have argued in favor of a vaccination program on the basis of such benefits. But the actual complications seen here and those generally reported[4,10] are usually self-limited, and serious sequelae are generally considered rare,[12,13,16] so it is less likely that this analysis has overlooked a large potential cost that would invalidate the conclusions. Reports of sterility, perhaps the most feared sequela in postpubertal males, are very sparse,[16] and it is therefore discounted.

The usual explanation for the recent rise in mumps incidence among secondary school and-college age populations is that there is a nonimmune cohort in the population that missed both mumps immunization and illness in the 1970s, when rates were falling and before states passed school vaccination laws which included mumps.[5,9] If this is the case, the frequency of mumps outbreaks should decrease after a few years, as this cohort passes into adulthood. In the interim, monitoring of Army mumps rates for any increase is indicated, and the 16 states that currently do not require mumps immunization for grade school enrollment[17] should be encouraged to enact such laws. While this study's perspective is necessarily narrow, in that only current disease costs are considered, it appears that Army mumps rates would have to more than double from 1986 levels before a blanket immunization program would be cost-beneficial. A current serological survey of the recruit population is planned to better address potential changes in requirements for mumps and other vaccines.

The Role of Secondary Vaccine Failures in Measles Outbreaks

Richard G. Mathias, MD, William G. Meekison, MD, Teri A. Arcand, and Martin T. Schechter, MD, PhD

Abstract: An outbreak of measles in 1985–86 in a community where measles vaccine trials had been carried out from 1974–76 allowed the assessment of the role of secondary vaccine failures in previously immunized children. A total of 188 children from the vaccine trial were followed. Of these, 175 seroconverted initially while 13 (6 per cent) required re-immunization (primary failure). A total of 13 cases of measles, eight of which were laboratory and or physician-confirmed, were reported in this cohort. Of these, nine cases occurred in the 175 subjects who had hemagglutination inhibition test (HI) and neutralizing antibody responses following the initial immunization. These nine cases represent secondary vaccine failures. An additional four cases occurred in the 13 subjects with primary vaccine failure. We conclude that secondary vaccine failures occur and that while primary failures account for most cases, secondary vaccine failures contribute to the occurrence of measles cases in an epidemic. A booster dose of measles vaccine may be necessary to reduce susceptibility to a sufficiently low level to allow the goal of measles elimination to be achieved. (*Am J Public Health* 1989; 79:475–478.)

Introduction

Measles virus has probably infected mankind since antiquity. Only recently has the introduction of a vaccine allowed the control of measles to be considered a goal of public health.[1–3] Panum[4] showed that immunity to wild measles virus was maintained even many years after infection. However, immunity following vaccine has been more problematic, with outbreaks of measles described in immunized populations virtually since the vaccine was introduced and widely used.[5–16] In all of these reports, failure of vaccine delivery was thought to be the major factor in the outbreak rather than failure of the vaccine itself. In those cases who had been immunized and developed measles, the reason was felt to be lack of seroconversion with initial immunization, primary vaccine failure, rather than loss of protection after seroconversion had occurred, secondary vaccine failure. The attack rates in the immunized of about 5 per cent were compatible with primary vaccine failure rates. Those individuals who do not seroconvert to measles vaccine and hence are possible primary vaccine failures may be detected by serology and given further vaccine if desired. Secondary vaccine failures who have seroconverted but are not protected cannot be so identified. Gustafson[17] has recently described an outbreak in Texas in a well-immunized population where primary vaccine failure was thought to be a more important factor than vaccine delivery.

We had the opportunity to study the incidence of measles in a population of children who had participated in measles vaccine trials and who had antibody studies carried out following immunization. We report here on the relative importance of primary and secondary vaccine failures on the incidence of self-reported measles in a well-immunized population in the 10 years following immunization. As present and future control of measles is highly dependent on the induction of immunity and the maintenance of protection to prevent measles,[18] these findings may indicate the possible success or failure of measles elimination programs.

The Setting

Boundary Health Unit (BHU), a public health unit funded by the Ministry of Health of the Province of British Columbia, serves a suburban and rural community close to the major metropolitan center of Vancouver. In 1985, the year of the start of the measles outbreak, there were 271,141 residents in the 480 square kilometer area administered by the unit. Of these residents, 8.1 per cent were under age 5, 16.7 per cent were aged 5–14 years, and 31.7 per cent were aged 25–44 years. The mean family income was $29,008. The mean family size was 3.0 individuals. There are 124 public and private schools with an enrollment of 34,218 in kindergarten to grade 7, and 21,178 in grades 8–12.

Vaccine trials were carried out from January 1974 to February 1976. There were approximately 6,000 one-year-olds in 1974–75 eligible for measles immunization at one year of age. Of the number potentially eligible, 382 volunteered for the study and were enrolled. Connaught Laboratories Limited of Willowdale, Ontario conducted the measles vaccine trials to compare vaccine produced by them to vaccine from Merck, Sharp, and Dohme, Ltd. Both vaccines contained a live further attenuated measles strain and both were given as a single product. Children were immunized at approximately one year of age after an initial serum specimen was drawn. A second sample was drawn one month later. Repeat samples were done in the immunized children who could be located at three and five years. All serum samples obtained in the vaccine trial were tested for hemagglutination inhibition and for neutralizing antibodies by Connaught.

While British Columbia has experienced a decline in the numbers of measles cases reported, outbreaks have continued to take place. A measles epidemic occurred in the province from 1984 to 1986 involving 7,479 reported cases for the 12 months from September 1985 to August 1986. Of these, a total of 744 cases were reported from the BHU (354 males and 390 females); 60 (8.5 per cent) were confirmed by the Virology Section of the Provincial Laboratory, BC Ministry of Health. The peak of the epidemic occurred from the end of January 1986 to the middle of March 1986 with cases occurring until the second week of June 1986. The mean age of reported cases was 12 ± 5.6 years. The largest proportion of cases (42.7 per cent) occurred in the age group 10–14 years.

Methods

During May–June 1986, all children who had taken part in the 1974–76 vaccine trials were identified from the trial

center's records. An attempt was made to contact them at their last known address using school lists to locate additional children. The child and his/her parents were contacted to obtain consent to participate in the follow-up study. For those who consented, a blood sample was obtained from the child, and a questionnaire was administered by study personnel to the child and a parent. The questionnaire sought information about the immunization history and possible cases of measles in the child and in family members. The children in the vaccine trial who were located and enrolled in the follow-up study will be referred to as the cohort.

The measles hemagglutination (HI) antibody levels and the measles neutralization titers were both determined by methods described by Gershon and Krugman.[14] The measles IgM (immunoglobulin M) levels were determined by a method adapted by Connaught Laboratories Ltd., and are on file.

Antibody levels were analyzed using geometric mean titer (GMT) as doubling concentrations had been used for all specimens in the vaccine trial. The samples were run in different years. Although the methods for HI and NA were similar over the time period, variations in materials and instruments makes direct comparison of levels in different years inadvisable. This is particularly true of the initial and 1986 samples. We have thus looked at samples within years and did not analyze titers serially.

Primary vaccine failure is defined for this paper as failure to have neutralizing antibodies following immunization, whether the first or subsequent immunization. Secondary vaccine failure is defined as a lack of protection in an individual who had documented neutralizing antibody titer ≥ 1:4 post-immunization. Seroconversion is defined as a four-fold or greater rise in hemagglutination titer, or a detectable titer in an individual who had no previous detectable antibodies.

Results

A total of 382 infants had been enrolled in the vaccine trials. Due to an unbalanced design, 265 received vaccine produced by Connaught, while 117 received measles vaccine produced by Merck. A total of 225 of the 382 families were contacted. Thirty seven gave information but no sample was obtained. Thus for the follow-up study, a total of 188 subjects (49.2 per cent of the vaccine trial participants) were located and had data and blood samples collected (cohort), while the remaining 194 (51.8 per cent) were not located or did not enter the follow-up study (lost). Of the cohort, 129 and 59 members had received Connaught and Merck vaccines respectively, the same ratio as in the original trial. As seen in Table 1, the cohort and lost groups were similar.

The proportion of the cohort and lost groups subsequently followed in the vaccine trials was 26 per cent of the cohort group and 8 per cent of the lost group recalled at a mean of 58 months for both groups. The titers for both groups at each follow-up period were similar except for higher HI and NA titers in the cohort group at 30.4 and 31.5 months respectively. By 58 months, the antibody titers in both groups were similar.

The mean age at immunization was 1.04 years for the cohort; 23 cohort members had more than one immunization; 13 were failures in the cohort group and 12 individuals were reimmunized as part of outbreak control measures. Seroconversion rates were similar for both vaccines.

Thirteen children in the cohort group (6.9 per cent) were reported to have had measles subsequently. One of these cases was laboratory confirmed. Neutralizing antibody had been demonstrated in this individual post initial immunization. Eight cases of measles in the cohort were confirmed by a physician. Among the 13 cases of measles, five had received Merck vaccine, eight Connaught. Of these 13 cases, two had measles at age 2, four at ages 6–8 (the 1980 outbreak), and seven at ages 10–12 (the 1985–86 outbreak).

As seen in Table 2, of the 13 subjects in the cohort who did not seroconvert initially to NA, 10 underwent repeat immunization with antibody testing and all 10 seroconverted. One of these 10 was reported to have had measles. There were an additional two infants who had neither a second immunization nor subsequent antibody titers (primary vaccine failures) and both of these children were reported to subsequently have had measles. The remaining child with measles received a repeat immunization but seroconversion was not documented; the latter child was also reported to have had measles. Overall, four of 13 (31 per cent) of those who were initial vaccine failures subsequently had measles. These four cases were all physician-confirmed and three occurred in 1985–86. In those whose follow-up antibody levels were considered protective, nine of 175 (5 per cent) subsequently had measles. These nine cases were secondary vaccine failures. Four of the nine cases were physician-confirmed and four were diagnosed in the 1985–86 outbreak. The attack rates (and 95% confidence intervals) in those who converted on initial vaccination and those who did not were 31 per cent (9, 61) and 5 per cent (2, 10), respectively.

In the cohort, the initial laboratory titers differed between those with and without subsequent measles (Table 3) in that both HI and NA titers were lower in the group who subsequently developed measles. This was observed both for those who had ever had measles and for those who had measles in the 1985–86 epidemic.

The results of the samples taken in 1986 indicated that the mean HI titers in the cohort members who reported measles was higher than in those who did not (geometric mean titer 30 vs 19). This was even more pronounced if only

TABLE 1—Comparison of 188 Children Followed from Original Vaccine Trial (cohort) and 194 Children Lost to Follow-up (lost)

Parameter	Cohort (%)	Lost (%)
Number	188	194
Mean Age at Immunization	1.04 ± 0.10	1.06 ± 0.14

*Initial refers to the sample following immunization in the vaccine trial; final refers to the 1986 follow-up sample.

measles cases with dates of onset in 1985–86 were used (40 vs 19).

The measles specific IgM results were negative for all 188 members of the cohort. Specifically, none of the seven who reported measles in the 1985–86 outbreak were IgM positive. The samples for the IgM determinations were taken 13 and seven months after reported disease in two individuals, four months post infection in three subjects, two months in one, and two weeks in the other. A positive result may have been expected in five of these cases.

Discussion

Although these children were originally enrolled in a vaccine trial, their subsequent experience with measles does not appear to have been due to the differences in vaccines being tested. The control product from Merck has been widely used in Canada and the US at that time and since. Although the Connaught vaccine was not marketed, the proportion of cases who seroconverted and who subsequently developed measles was not significantly different from the Merck immunized children. The similarities in the located and not located groups within the vaccine trial population indicate that a bias in the follow-up is not likely to account for the experience of the cohort with respect to measles.

All of these children had neutralizing antibody detected postimmunization although only 95 per cent seroconverted with the first immunization as might be expected.[18,20] All of these children would conventionally be considered protected including those who required re-immunization.[21] In those in whom seroconversion had been documented, any subsequent measles must be considered a secondary vaccine failure as defined by Frank, *et al*.[22] Although documented by Cherry,[5] Frank, *et al*,[22] did not consider secondary failure a major contributor to the measles elimination program failures.

The measles experience of this cohort was considered over the life experience of the child. With the difficulty in making the clinical diagnosis of measles, this may result in the overestimation of the number of cases. Nevertheless, the reported cases in the cohort took place during reported measles outbreaks in British Columbia. During the recent outbreak there was one laboratory-confirmed and a number of physician-confirmed cases reported. Following the measles, HI antibodies demonstrated a rise over time in those reporting measles compared to those not reporting measles. All of these observations would tend to validate the cases reported. We conclude that the reported cases in the cohort represent measles in children who had seroconverted and hence are secondary vaccine failures.

Within the cohort, there were predictors of subsequent measles. Children who required re-immunization because of an initial vaccine failure were six times as likely to have measles as those who seroconverted with a single dose. Even after seroconversion, the mean titers of seroconverters who reported measles in the 1985–86 outbreak were less than those who did not report measles (HI 35.8 vs 8.8; NA 19.2 vs 7.2). These data indicate that the initial immunization response predicts subsequent risk of measles and that the risk depends on both seroconversion and on the titer of antibody produced at approximately one month following immunization. These low titers may become undetectable more quickly than higher titers although other investigators have not found that time from immunization was a factor in measles outbreaks.[6,23–25]

In our cohort, none of the five recent cases was found to be IgM positive. Nagy, *et al*.[23] found IgM responses in 77.4 per cent of those who had been vaccinated. They concluded that those who had an IgM response represented a primary vaccine failure, whereas those with HI increases or a high titer were secondary vaccine failures. Gustafson, *et al*,[17] found cases only in the group seronegative early in the epidemic, with all appropriately tested cases IgM positive. They concluded that, as no cases occurred in the seropositive group, the outbreak they investigated was due to primary vaccine failures. The situation in our outbreak was markedly different as 184 of 188 individuals in the cohort were known to be seropositive following immunization. Although it is possible that all of the cases of measles occurred in those who had lost antibody, as explained by the lower initial titers in the cases,[24,25] we could not confirm this. The lack of IgM response in our group is in contrast to the data of Gustafson[17] and Nagy,[23] although the very small numbers in our group make this lack of an IgM response imprecise. The pre-existing antibody titer results on our cohort confirm that secondary vaccine failure was important in our study population.

The ultimate control of measles has been predicted with models developed by Anderson and May[26] and Levy[16]. The role of secondary vaccine failure has not been considered in these models. Neither was it considered important by Frank, *et al*.[22] We feel that the documentation of an attack rate approximating 6 per cent over the 10–12 years post-immunization in a cohort of individuals with known primary vaccine seroconversion must prompt further study into the role of secondary vaccine failure in measles outbreaks. Nkowane, *et al*,[6] found that at least 48 per cent of their cases occurred in adequately immunized individuals. Although the outbreak they investigated lasted only four generations, they concluded that vaccine failures played a role in transmission.

If a significant role is established for secondary vaccine failure, this must be taken into account in the predictions of measles control programs. The assumption that measles immunity as induced by vaccine is as high as the seroconversion rate appears to be an overestimate of the true situation. Routine booster immunization of all children rather than for select groups,[24] in order to reduce the numbers of primary vaccine failures and to boost the titers in all children, may be necessary to eliminate measles. It is clear that reliance upon measles antibody studies, even when neutralizing antibody is measured, only gives an estimate of the immune status of the individual. The clarification of the constituents of immunity to measles may allow the develop-

ment of vaccine which will more closely stimulate the same immune response that is induced by wild measles infection. Until this is done, it appears that we will continue to see measles epidemics in well-immunized populations and that these epidemics will be due to both primary and secondary vaccine failures.

New Fellowship to Honor Creativity in Managed Health Care

An annual fellowship grant has been established by the Caldwell B. Esselstyn Foundation to honor an individual who demonstrates exceptional creativity and scholarship in the field of managed health care. To be awarded for the first time in July 1989, the fellowship—which could total as much as $35,000—will provide seed money for development of a new project or program to benefit staff or group model HMOs. The foundation is named for a pioneer in the prepaid group practice movement.

To obtain an application for the fellowship, write or call the Caldwell B. Esselstyn Foundation, 1201 Troy-Schenectady Road, Latham, NY 12110. Tel: (518) 783-1864. Completed applications must be submitted by May 15, 1989.

Illness Associated with Child Day Care: A Study of Incidence and Cost

David M. Bell, MD, Dennis W. Gleiber, PhD, Alice Atkins Mercer, PhD, Robi Phifer, MFA, Robert H. Guinter, MD, A. Jay Cohen, MD, Eugene U. Epstein, MD, and Manoj Narayanan, MD

Abstract: We studied 843 children under 36 months of age enrolled in a prepaid health plan from September 1985 through March 1986, to identify characteristics of day care which might be risk factors for infection and to describe the resulting economic costs. Children cared for in their own home had a mean of 2.03 infections diagnosed during the study period. Adjusted rates of excess infection (95 per cent CI) for children cared for in other settings were: −.09 (−.73, .54) in relatives' homes; .10 (−.51, .71) in day care homes; .79 (.13, 1.45) in day care centers; .60 (−.24, 1.46) in mother's day out programs; and .66 (−.01, 1.34) in multiple settings. Children in day care centers were 4.5 times more likely to be hospitalized than those in other settings (95 per cent CI = 1.55, 13.00), primarily due to an increased rate of tympanostomy tube placement (relative risk 3.79, 95 per cent CI = 1.04, 13.36). The strongest predictor of illness risk was the number of other children in the room. The mean monthly cost of medical care was $32.94 for children in the highest risk settings compared with $19.78 for those in other settings. Illness in a child in our study accounted for 40 per cent of parental absenteeism from work; the mean number of days lost per month was 0.52 for parents of children in day care centers compared with 0.37 for those of children in other forms of full time care outside the home. (*Am J Public Health* 1989; 79:479–484.)

Introduction

Day care for preschool children of working parents has become an integral part of American life. More than half of all mothers with preschool children are in the labor force and more than 60 per cent of their children receive day care outside the home.[1] Many studies show an increased risk of infection for children and their families using at least one form of care—the institutional day care "center".[2–10] A lower risk of illness has been attributed to children cared for by non-relatives in private households known as day care "homes", but few data are available from these settings which are typically small, often unlicensed, and difficult to identify.[5–9]

Reliable measures of the risks and consequences of infections attributable to various forms of child care are needed. Most reports have focused on only a single pathogen or disease, studied day care centers exclusively, or used case-control methods to estimate relative risk of illness rather than prospective surveillance to generate incidence data. With some exceptions,[11–14] most studies have not evaluated specific characteristics of child care which might promote the spread of infection. Finally, despite the fact that child care has become an economic necessity for many families, the economic consequences of varying illness rates among children in different settings have not been examined.

During the winter of 1985–86, we studied a cohort of preschool children in our practice who were enrolled in a prepaid health care plan to compare the incidence of illness among children cared for in different settings, to study the economic consequences of child care-related illness, including increased utilization of health care services and parental absenteeism from work, and to identify characteristics of child care which may be important determinants of illness incidence and health care costs in preschool children.

Methods

The children in our study received prepaid medical care from the Health First Medical Group (HFMG), a 28-physician multi-specialty group having three offices in middle class areas of Memphis, Tennessee. The children studied were all insured under a family health care plan offered through a parent's employer which stipulated that all medical care, in order to be covered, had to be provided or authorized by an HFMG physician. Parents, employers, or both paid a single monthly premium, in exchange for which the costs of all visits to an HFMG office, including laboratory and x-ray studies, as well as referrals to specialists and hospitalizations were covered at 100 per cent with no deductible. Authorized emergency room visits were also covered but incurred a $25 copayment. Prescriptions written by HFMG physicians could be filled immediately at in-house pharmacies for a fee of $3 each. These features were designed to provide strong incentives for patients to obtain all of their medical care from the HFMG.

An HFMG office is located within 20 minutes driving distance of all areas of Memphis and its suburbs. To facilitate access to medical services, HFMG offices are open weekdays from 8:30 am until 9:00 pm, and weekends and holidays from 1:00 to 5:00 pm. A 24-hour telephone consultation service is also available.

Study Design and Data Collection

During the seven-month period September 1985 through March 1986, health care utilization data for all children under 36 months of age enrolled in the prepaid plan were collected prospectively without their parents' knowledge that a study was in progress. Information regarding illness diagnosis and laboratory and x-ray studies (obtained if necessary for patient care) were recorded on computerized encounter forms by the examining physician at each HFMG office visit. For this study, common infectious illnesses were classified as: 1) upper respiratory infection without otitis media; 2) lower respiratory infection; 3) acute otitis media; 4) gastroenteritis; and 5) skin infection. We distinguished follow-up visits for the same illness from separate illnesses.

Medical charges were abstracted from the encounter forms; these were charges which would have been billed directly to other HFMG patients not members of the prepaid health care plan. Diagnoses and charges resulting from authorized emergency room visits and hospitalizations were obtained subsequently from hospital and insurance records. The average retail cost per visit of drugs prescribed for children during the study period was obtained from pharmacy

records. Immediately following the study period, a letter explaining the project and a questionnaire were mailed to parents of all subjects. The questionnaire requested information on child care arrangements for the index child, including household characteristics and other variables which might affect the child's risk of illness (Appendix A). We also asked the number of days and the reasons for which a parent had been absent from work during the preceding three months, the cost of day care for the child, the number of visits the child had made to non-HFMG physicians or emergency rooms during the preceding month and the number of times the child had been ill without seeing a physician during this month. Two weeks after the questionnaires were mailed, a computer generated random sample of 15 per cent of parents who had not responded were interviewed by telephone. This survey was performed by trained interviewers who explained the purpose of the study and administered the questionnaire using a standardized, closed-ended format.

We excluded from the study only those children diagnosed by one of us as having a chronic illness which might lead to increased susceptibility to infection (including asthma, bronchopulmonary dysplasia, congenital heart disease, cystic fibrosis, and Down's syndrome).

Tympanostomy tubes were placed by a single otolaryngologist after referral by one of us for indications of either recurrent episodes of acute otitis media despite daily prophylaxis with antibiotics, or middle ear effusions persisting despite three months of medical treatment. Patients who had received tympanostomy tubes within eight months before onset of the study were excluded from the tabulation of otitis media incidence; patients who received them during the study were excluded from this tabulation for the remainder of the study.

Statistical Methods

Bivariate analysis of illness incidence according to type of child care was performed using the F test for analysis of variance. Rates of excess illness in children cared for outside of their own homes were adjusted using linear regression analysis for the effect of host and family environment variables which differed among children in different forms of care.

Hierarchical multiple linear regression analysis was used to evaluate potential risk factors for diagnosed illness in children who were cared for outside of their homes by non-relatives. Independent variables (Appendix A) were entered into the model in sequential groups of host, family environment, and then child care characteristics and were retained in the model using backward elimination if their p values were $<.05$ (two-tailed).

The suitability of linear regression for modeling non-normally distributed dependent variables (illness incidence) was validated by examination of the error terms. No serious deviation from normality was observed in these terms, and plots of residual terms and predicted values displayed no violation of the homoscedasticity assumption.[15,16]

Results

Cohort Members, Child Care Settings

Of 1,388 children under 36 months of age when the study began, 57 (4.1 per cent) were excluded due to chronic illness. Of the remaining 1,331, data were obtained by mail for 758 (57 per cent) and by telephone for an additional 85 (6 per cent). As there was no difference of consequence in the distribution of child care settings between these two groups of respondents (Appendix B), we combined them to yield a total of 843 children (63 per cent of the target population) upon whom our analysis is based.

Of the 843 children studied, the age distribution at entry was 33 per cent 0–11 months, 34 per cent 12–23 months, and 33 per cent 24–35 months; 48 per cent were male; and 57.5 per cent were White, 39.8 per cent Black, 0.1 per cent Hispanic, 1.2 per cent Asian, and 1.2 per cent of other or unspecified race. (In comparison, US Census data indicate that in 1980, the population of Shelby County, Tennessee, which includes Memphis, was 57.3 per cent White, 41.8 per cent Black, and 0.9 per cent of other or unspecified race.) Eighty-two per cent of the children studied lived in households with two adults, 11 per cent lived with only a single adult, and 7 per cent lived with three or more adults. Of the 685 households containing two adults, both adults were employed in 68 per cent.

The customary source of child care varied widely (Table 1), as did host and family environment characteristics of children in different forms of care (Appendix C). Compared with children enrolled in day care centers or mother's day out programs, those enrolled in day care homes were more likely to be permitted to attend if they were febrile (134/185 vs 43/200; odds ratio 9.6; 95 per cent CI = 5.9, 15.8), had symptoms of respiratory illness (162/185 vs 139/200; OR 3.1; 95 per cent CI = 1.8, 5.4), or had vomiting or diarrhea (102/185 vs 38/200; OR 5.2; 95 per cent CI = 3.2, 8.6).

Incidence of Illness and Associated Risk Factors

Bivariate analysis disclosed differences in infection rates according to child care setting (Table 2) which persisted after

TABLE 1—Child Care Arrangements of Study Participants

Child Care Setting	Number of Children Studied (%)	Mean Number of Hours Week in Child Care	Mean Number of Other Children in Room	Mean Cost per Week (Dollars)

adjustment for potentially confounding host and family environment variables (Table 3). Hospitalization rates were unaffected by age and were higher for children in day care centers than for children in all other settings combined (relative risk = 4.50, 95% CI = 1.55, 13.00), primarily due to an increased incidence of tympanostomy tube placement (relative risk = 3.79, 95% CI = 1.04, 13.36) (Table 4).

Multivariate analysis identified the following predictors* of the total number of infections diagnosed: age in months (B = −.07, SEB = .01), breastfeeding prior to the study (B = .86, SEB = .24), median household income of census tract in $1000's (B = .094, SEB = .021), number of other children in the room in child care (B = .05, SEB = .02), lack of a separate room for diaper changing/potty use (B = .76, SEB = .28), and food furnished by the child care provider (B = .81, SEB = .37). Results were similar for individual categories of infection except that no child-care variables were predictive of upper respiratory infection without otitis media and presence of infants less than 12 months of age, acceptance of children with vomiting or diarrhea, and bringing food from home were predictive of gastroenteritis.*

No risk factors for skin infection were identified. Host, family environment and child care variables, respectively, accounted for 10, 4 and 5 per cent of the variance (R^2) in total number of infections diagnosed. Entry of an additional set variable, "child care setting", into the multivariate model resulted in a net increase in explained variance of only 0.7 per cent, suggesting that most of the variance attributable to child care was accounted for by variables specified in our model.

*Complete data from multivariate analyses are available from authors on request. B = unstandardized regression coefficient, SEB = standard error of B.

Financial Costs

The mean monthly cost of medical care, including prescription drug costs, for children in the highest risk settings (day

care centers, mother's day out programs, and multiple child care settings) was $32.94, compared with $19.78 for other children (Table 5). Parents reported being absent from work a mean of 0.40 days per month between January and March 1986, of which a mean of 0.16 days (40%) was due to illness in a child in this study. The mean number of days absent from work per month because of illness in a child in this study was 0.52 for children in day care centers compared with 0.37 for children in other forms of full time day care outside the home (i.e., day care homes or relatives' homes).

Discussion

Our finding of an increased incidence of illness in children attending day care centers, but not day care homes, is consistent both with previous reports[5–9] and with the results of our multivariate analysis, which suggest that the major risk factor for infection in a child care setting is the number of other children in the room.

Our study has certain potential limitations. First, illness ascertainment bias may have been introduced if children in certain forms of child care were more likely to seek medical attention when ill or if, despite the incentives of the prepaid plan, they were more likely to make an unauthorized visit to a physician outside of our group. Our questionnaire data for one month within the study period suggested that neither of these possibilities occurred. Since symptoms in young children may be non-specific, a strength of our study was that illnesses were diagnosed by a physician.

Second, information on child care settings came from parents rather than from day care providers. We believed that the answers to our questions would be readily known to the parents and that they would respond truthfully to their child's pediatrician. This impression was corroborated by the prompt, unhesitating responses obtained in the telephone survey and by the fact that the average completion rate for questionnaires returned by mail was over 95 per cent.

Third, some risk factors identified in our multivariate model may actually have been proxies for other variables that were not studied. For example, the curious observation that a history of breastfeeding in the past was associated with a higher incidence of both total infections and upper respiratory infection without otitis media might be explained if breastfeeding, or its discontinuation, was a proxy for lack of immunologic experience or for a constellation of sociocultural practices that we could not better identify, but which led to an increased infection rate in the preschool years.

Finally, the financial data reported in this study pertain to families in Memphis, Tennessee enrolled in a prepaid health plan. These figures may not be applicable to other areas of the United States where medical charges may be different or to children covered by other types of health insurance in which there may be financial barriers to seeking medical care or different practicing styles of participating physicians. Our financial data, like our illness incidence data, are most useful in offering estimates of the magnitude of differences among children in different child care settings within a single study population. Our data indicate that there are certain potentially modifiable characteristics of day care which are risk factors for illness and that excess illnesses result in excess financial costs. The health of children in day care should be of concern not only to parents, physicians, and public health officials, but also to employers and health insurors who might find it worthwhile to subsidize the possibly increased cost of child care in settings designed to minimize illness rates.

*Reported for 651 children for whom the income of the parent staying home from work was known.
†To care for an ill child in this study.

APPENDIX A
Variables Entered into the Multivariate Models for Incidence of Infection

Host Variables

Age (months)
Sex
Breastfeeding during study
Breast-fed prior to study
Length of time (months) in child care prior to study

Environmental Variables

Median household income of census tract of residence
Sibling in day care
Number of household members in the age groups
< 12 months, 12 months–4 years
Household crowding index (people per room)
Number of smokers in household

Child Care Variables

Hours per week in child care
Number of other children in room
Age group(s) of other children in room
(< 12 months, 12 months–4 years)
Children caregiver ratio in child's room
"Drop-in" children permitted
Child accepted with: 1) respiratory symptoms
2) vomiting or diarrhea
Food furnished by child care provider
Food brought from home
Separate room for diaper changing, "potty," and toilet use
Caregivers known to smoke in room with children
Cost per hour of child care

Child Care Settings

Day care home
Mother's day out program*
Day care center
Multiple settings

*A form of group care common in the Memphis area, usually sponsored by a church one or two days per week.

NCHS Quarterly Report Cites New Publications, Findings

The National Center for Health Statistics recently announced, in its Quarterly Report, several new publications to be available from the Center in February 1989. These include the following:

- *Characteristics of Nursing and Related Care Homes: The 1986 Inventory of Long-Term Care Places*. (Describes facility characteristics such as ownership, certification status, numbers of beds and residents. Examines occupancy rates, per aged population, and numbers of Black and Hispanic residents.)
- *The National Nursing Home Survey: 1985 Summary for the United States*. (Provides descriptive tables on characteristics of nursing homes, registered nurses at the facilities, current residents, data on cost of providing care, health and functional status of residents, payment for care.)
- *Children of Divorce*. (Analyzes trends in the number and proportion of children whose parents are divorced, as well as characteristics of divorcing couples with and without children, and geographic variations.)
- Also, Coming Soon: *NCHS 1988 Year in Review* (A new publication featuring two series of articles published during 1988 on NCHS data and programs. And an overview of surveys conducted and information available from NCHS for 1988.)

To be included on an NCHS mailing list, or to receive copies of any of the reports listed above, write or call:

Recurrent Outbreaks of Giardiasis in a Child Day Care Center, Wisconsin

Richard W. Steketee, MD, MPH, Steven Reid, MD, Tina Cheng, MD, James S. Stoebig, MS, Richard G. Harrington, MS, and Jeffrey P. Davis, MD

Abstract: In the 19-month period September 1983–March 1985, three outbreaks of giardiasis occurred in one large child day care center. Control measures instituted during each outbreak included case finding; pharmacologic treatment and follow-up testing of stool specimens for cases of giardia infection in day care children and staff, and their household contacts; facilitating and stressing personal and environmental hygiene, including altering diapering practices and teaching appropriate hand washing techniques. In the first, second, and third outbreaks, overall attack rates (stool analysis positive for *Giardia lamblia*) were determined for those persons with ≥2 stool specimens submitted; attack rates in children were 47, 17, and 37 per cent, respectively; for tested staff, the rates were 35, 13, and 9 per cent; and for tested household contacts were 18, 9, and 5 per cent. Attack rates were highest for ambulatory diapered children, children attending the day care center ≥40 hours per week, and children who were infected with *G. lamblia* in the most recent previous outbreak. Despite extensive efforts to identify cases, a cure rate of >90 per cent in treated cases, and improvements in personal and environmental hygiene practices, *G. lamblia* infections recurred in outbreak proportions. (*Am J Public Health* 1989; 79:485–490.)

Introduction

Gastrointestinal infections associated with child day care have been of increasing interest in the United States in recent years, and diarrheal illness caused by *Giardia lamblia* has been noted frequently.[1] Within the child day care setting, efforts to understand the occurrence of giardiasis have included assessing the incidence and the prevalence of *G. lamblia* infections,[2–6] the extent of symptomatic illness,[2,3,5] the modes of transmission,[2,4,7,8] the specific risk factors for acquisition of *G. lamblia* infection,[2,5,6] and the appropriate control measures.[2,5,9–11]

In September 1983, an outbreak of symptomatic giardiasis was detected in a proprietary child day care center in Wisconsin. Control measures included: case finding in symptomatic and asymptomatic children, staff, and household contacts of infected children; pharmacologic treatment and follow-up test-of-cure of all cases of *Giardia* infection; and health education for staff, including regular teaching of personal and environmental hygiene. A second outbreak of giardiasis was detected in this day care center within eight months of the first outbreak and a third outbreak occurred eight months after the second outbreak. We present here a description and evaluation of the giardiasis outbreak control measures in this day care setting.

Background

During the interval from September 1983 to March 1985, this day care center in suburban Dane County, Wisconsin provided care for children ages 1 month to 6 years and had an average daily census of 115 children of whom 45 per cent were toilet trained. The facility is licensed for the care of 175 children and the enrollment ranged from 100 to 167 children during the 18-month interval. The fluctuation in enrollment was due largely to changes in the number of preschool and kindergarten children, while the number of infants and toddlers remained relatively stable. Children came from predominantly middle-income households in neighborhoods surrounding the center. The average child-staff ratio was 7.6 to 1 (range 6.6 - 10.4 to 1), the center provided an average of 59 square feet of classroom space per child (range 40.6–60.6 square feet per child). Play groups were organized by age groups as shown in Table 1 with 10 to 15 children within a play group; each play group was located in a separate classroom. Mixing of play groups occurred occasionally during outdoor playtime, but was otherwise uncommon. The day care center staff worked only with their assigned play group and had minimal contact with other play groups.

The center's staff maintained daily records of bowel movements for children ≤36 months old and the stool consistency was noted to be formed, loose, or watery; the parent was informed if the child had a perceived change in bowel habits or watery diarrhea. The day care center's management policy for children with diarrhea included notifying parents and strongly encouraging exclusion of symptomatic children. Although compliance with this policy was not routinely documented, staff felt that parents nearly always accepted the policy. Due to limitations of space and staff supervision, cohorting of ill children was not practiced. At the time of the initial outbreak investigation, food handlers also provided child care. Diaper changing occurred in the classrooms and, except in the infant rooms, running water was available only in bathrooms. A bucket of water was used for washing the diapering table and for hand washing after diapering. The water bucket was emptied and refilled between diaper changes.

Methods

Case Finding

On September 2, 1983, the director of the day care center reported that four children in one play group had developed a diarrheal illness, and that 33 per cent of 87 infants and toddlers had experienced diarrhea in the previous two weeks. After obtaining parental consent, stool specimens for bacterial and parasitic pathogen testing were collected from these four children by the local public health agency; *G. lamblia* was the only enteric pathogen identified in their stool specimens. With support from the local public health agency, efforts were made to collect two or more stool specimens from all symptomatic day care center attendees and six

*Testing in preschool groups during outbreak B and C included only symptomatic children and children who had DCC attending siblings with cases giardiasis.
‡Household contacts included current permanent residents in households with a DCC case of giardiasis.
†Tested with ≥2 stool specimens.

additional persons with *G. lamblia* infections were identified. Stool specimens were then collected from asymptomatic day care attendees in the same play groups as known cases. Investigation and public health measures were instituted and this outbreak (outbreak A, see definition below) ended in late October 1983. Two additional outbreaks of giardiasis were identified in this center in the following 17 months: outbreak B occurred in June–July 1984, and outbreak C occurred in January–March 1985. Each outbreak was identified and evaluated in the same manner by local and state public health officials.

Definitions

- A *case* of giardiasis was defined as infection (with or without symptoms of diarrhea) in any attendee, staff, or household contact with laboratory confirmed *G. lamblia* in ≥1 stool specimen.
- A *non-case* was defined as person with ≥2 stool specimens collected more than 24 hours apart that were negative for *G. lamblia*.
- *Diarrhea* was defined as an increased frequency of stools with a change in consistency of stools to watery or loose as reported by parents or day care center staff. Center staff used this definition in routine surveillance for diarrhea in the day care center.
- An *outbreak* of giardiasis was defined as an increased prevalence of diarrheal illness among day care attendees with laboratory-confirmed *G. lamblia* infection in >20 per cent of screened attendees (with or without symptoms) in any age or play group. Although staff maintained records of day care attendee bowel movements during the day, these records were not retained more than two weeks. Thus, the "increased prevalence of diarrhea" in this definition relied on staff perception of an increase.
- An *outbreak* was classified as ended when the prevalence of diarrhea in day care attendees was reduced to "pre-outbreak levels" and no new cases were identified within a two-week period. Again, "pre-outbreak levels" relied on staff perception, but could be verified as lower than the point prevalence of diarrhea during the outbreak by reviewing bowel movement records which were maintained throughout the outbreak.
- The *timing of outbreak* onset and termination was established based on the combined requirement of increased prevalence of diarrheal signs and symptoms coupled with laboratory results, thus dates for each of the outbreaks are given by month rather than day or week of onset and termination.

Control Measures

Control measures used during the outbreaks included systematic case identification among day care attendees, staff, and household contacts of cases, using the algorithm in Figure 1. Persons with confirmed giardiasis were treated for 7–10 days by their physician with quinicrine hydrochloride, furazolidone, or metronidazole.* Parents of a case-child were asked to keep the child at home until the diarrhea resolved. Three weeks after completion of treatment, two test-of-cure stool specimens obtained >24 hours apart were examined for *G. lamblia* cysts. Retreatment was instituted as necessary until two stool specimens collected >24 hours apart were negative. Staff-cases were treated in similar fashion with medication, excluded while symptomatic, and given test-of-cure follow-up. Household-cases were treated in similar fashion with medication and the test-of-cure follow-up.

During outbreak A, changes were made in the center's routine to interrupt *Giardia* transmission. A public health nurse met with the staff of the day care facility to provide education regarding the signs, symptoms, and methods of diagnosis of *Giardia* infection, and the methods of prevention or interruption of transmission including personal and environmental hygiene. A public health nurse made follow-up visits to the center several times each week during the outbreak and at least monthly during the non-outbreak periods. Within the center, the diapering areas were moved closer to the sinks to facilitate hand washing and cleansing of diapering tables. Diapering areas were supplied with paper to be placed under each child during diapering and discarded after each diaper change. Food handlers were excluded from child care responsibilities. Appropriate hand washing procedures were taught and stressed by a public health nurse during follow-up visits and written guidelines for handwash-

FIGURE 1—Guidelines Used for Investigation and Pharmacologic Intervention in Day Care Center (DCC) Outbreak of Giardiasis, Wisconsin

ing practice were posted in the day care center. No change was made in the practice of monthly washing of all day care center toys.

The control measures used in outbreak A were also employed in outbreaks B and C, except that testing in children ≥3 years old was limited to symptomatic children or siblings of known *Giardia*-positive children in the center.

Investigation Methods

Information collected from the center's records for each attendee included name, age, gender, toilet training status, number of hours per week at the center, and date of initial enrollment. The day care staff provided information on the child's gastrointestinal signs and symptoms during the previous four weeks. During outbreaks B and C, we reviewed our records from the previous outbreak to determine the case status of the child during the most recent previous outbreak.

Laboratory Methods

In each outbreak, stool specimens were obtained from the initial symptomatic day care attendees and were tested for bacterial enteric pathogens (*Salmonella*, *Shigella*, *Campylobacter* and *Yersinia* species) and for ova and parasites; testing for enteric viruses was not done since routine stool testing in this setting was designed to identify pathogens which require specific antimicrobial therapy. In each outbreak, *G. lamblia* was the only pathogen detected and subsequent screening was for *Giardia* only. Two or three stool specimens were collected >24 hours apart in the day care center or at home and placed in a vial containing formalin. The specimens were centrifuged and the concentrate was examined for 3–5 minutes by light microscopy by a parasitologist. Specimens were examined both unstained and stained with trichrome stain.[12] If no *G. lamblia* cysts were seen, the stool concentrate was reconstituted in formalin-ether,[13] centrifuged a second time, and re-examined in the same fashion. Stools were considered positive if any *G. lamblia* cysts were seen. Test-of-cure stool specimens were examined in the same fashion.

Data Analysis

Comparisons of attack rates in different groups are presented as incident rate ratios (IRR) with 95% confidence intervals (CI).[14]

Results

Table 1 summarizes the *G. lamblia* attack rates for the three outbreaks. In outbreaks A, B, and C, *G. lamblia* was identified in stools of 47 per cent, 17 per cent, and 37 per cent of tested children; 38, 13, and 9 per cent of tested staff, and in 17, 9, and 5 per cent of tested household contacts, respectively. Among day care center children, *Giardia* infections were most common in Toddler Groups 1 and 2 (ages 18–23 months [38 per cent positive] and 24–29 months [48 per cent positive]), and were least common (17 per cent) in the infant group.

The *Giardia* attack rate (43 per cent) for 75 children attending day care ≥40 hours per week was significantly greater than the rate of 10.5 per cent for 137 children attending <40 hours per week, (IRR = 4.17, 95% CI 2.17, 8.47); this association was seen in all age groups.

Completed questionnaires were obtained for a total of 217 children with known symptoms and case status. Diarrhea within four weeks of recognition of the outbreak was reported in 35 (51 per cent) of 68 *G. lamblia* infected children and 42 (28 per cent) of 149 non-case children (IRR = 1.83, 95% CI 1.13, 2.93). Case children were more likely than non-case children to report symptoms of abdominal cramps, 13 percent versus 4 per cent, respectively (IRR = 3.29, 95% CI 1.05, 11.22). No significant differences between case children and non-case children were observed for other reported symptoms (respectively, vomiting in 0% and 1%; fever in 1% and 0%; loss of appetite in 12% and 5%; and "gas" in 9% and 3%). Among the *Giardia* infected children, 49 per cent were asymptomatic.

Information on the use of drug treatment was available for 89 case-persons (children and staff) and 81 (91 per cent) were treated with medication. Two negative test-of-cure stool specimens were obtained for 52 per cent of treated individuals and an additional 33 per cent had one test-of-cure negative exam. Table 2 shows treatment results for 67 persons for whom the specific medication and dose was known. The three drugs (metronidazole, furazolidone, and quinacrine hydrochloride) produced an overall >90 per cent cure rate in the 64 persons who had ≥1 test-of-cure stool examination.

At the time of detection of outbreak B, 37 (54 per cent) of the 69 tested day care children were newly enrolled after outbreak A, and at the time of outbreak C, 29 (45 per cent) of the 64 tested day care children were newly enrolled after outbreak B. During the two months of the outbreak A investigation, only 77 (57 per cent) of the center children attended throughout the outbreak, while 28 (21 per cent) enrolled during the outbreak and 29 (22 per cent) withdrew from the center during the outbreak. During outbreak A, attack rates were similar for those who stayed throughout and those who withdrew (52 and 50 per cent, respectively) and were lower in the newly enrolled children (25 per cent).

Attack rates by case status during the previous outbreak are shown for outbreaks B and C in Table 3. The day care center children in whom cases occurred during the previous outbreak were more likely to be case individuals than

*M = metronidazole, F = furazolidone, Q = quinicrine hydrochloride.
†Two or more follow-up stool specimens were available on 46 (69%) persons and an additional 18 (26%) had only one follow-up test. All failures were identified on first follow-up specimen.

children who were previously not cases individuals or children who were new arrivals into the center. Eight of the center children had *Giardia* infection during two consecutive outbreaks. Six of these children had ≥2 negative test-of-cure stool specimens, one child had one negative test-of-cure specimen, and one child had no post-treatment follow-up between the first and second infection. At the time of their second documented infection, four children had diarrhea and four were asymptomatic; this is no different from the rate of symptomatic *Giardia* infection in previously negative children or new enrollees. The one staff person with recurrent infection had three negative stool specimens between her first and second infection; she was asymptomatic during both infections.

Compliance with the personal and environmental hygiene control measures was not measured systematically; however, public health nurses observed proper handwashing techniques during their follow-up visits and diapering practices were altered during outbreak A and maintained thereafter as described above.

Discussion

Following efforts to control a day care center outbreak of giardiasis including extensive case-finding, high rates and success of pharmacologic treatment of cases, and changes in personal and environmental hygiene practices, *Giardia* outbreaks were observed to end but subsequently recurred on two occasions within eight months of the preceding outbreak. Possible impediments to effective control efforts included the new enrollment of infected children into the center, the continued shedding of *Giardia* by children or staff awaiting treatment, and environmental or design limitations of the facility which required staff to use buckets of water for handwashing and cleaning the diaper changing table. Although we cannot implicate a specific problem with the control measures used and we did observe a decrease in the prevalence of diarrhea and *G. lamblia* infection after instituting the measures, our findings suggest that treating all identified *G. lamblia* cyst passers in conjunction with alterations in handwashing and diaper changing practices did not permanently eliminate giardiasis transmission in this day care facility.

During these investigations, the designation of an outbreak of giardiasis in the day care center required a staff-perceived increase in diarrheal symptoms and laboratory confirmed *G. lamblia* in >20 per cent of day care children in one or more play groups. Only symptomatic children and their play group contacts were tested; the overall prevalence of infection in the center was lower than 20 per cent. Although studies in the southern US[4] have shown point prevalence rates of >20 per cent in day care centers without staff-perceived increased diarrhea prevalence, this has not been observed in Wisconsin (unpublished findings) or to our knowledge elsewhere in the northern US. Consequently, our definition was used as a guideline for public health intervention in Wisconsin and may not be applicable elsewhere in the country.

The determination of an outbreak may also have been limited by the lack of testing for a variety of viral enteric pathogens. Diarrhea within the previous four weeks was reported in 28 per cent of children without *G. lamblia* infection. It is possible that the some of the increase in diarrheal stools in day care attendees was due to a viral pathogen(s) or other etiologic agents and that *G. lamblia* was found as an incidental organism in some of these children. Regardless of the potential presence of additional pathogens, *G. lamblia* was detected in a high proportion of children with

TABLE 3—Giardiasis Attack Rates (AR), for Day Care Center Attendees in Outbreaks B and C, by *Giardia* Case Status During Prior* Outbreak

Outbreaks	New children enrolled since prior outbreak: Number	Cases in new children: No.	Cases in new children: (AR)	Children with case in prior outbreak: Number	case this outbreak: No.	case this outbreak: (AR)	Children with no case in prior outbreak: Number	case this outbreak: No.	case this outbreak: (AR)
B	37	5	(14%)	14	5	(36%)	18	2	(11%)
C	29	4	(14%)	5	3	(60%)	30	11	(37%)
TOTAL	66	9	(14%)	19	8	(42%)	48	13	(31%)

The incident rate ratio (IRR) for comparison between groups is as follows:

Comparison	IRR	95% CI
Child previously present and positive vs new child	3.0	1.04, 9.02
Child previously present vs new child	2.30	1.01, 5.70
Child previously positive vs child previously negative	1.35	0.56, 4.05

*Prior outbreak refers to most recent outbreak preceding this outbreak. One child had a case of *Giardia* infection in all three outbreaks.

diarrheal illness and was the only detected pathogen amenable to antimicrobial therapy. Thus, the short-lived effect of antimicrobial therapy as evidenced by the resumption of high *G. lamblia* prevalence demonstrates the limited benefit of this treatment as a control measure.

Giardiasis control efforts during these outbreaks depended in part on prompt diagnosis and treatment of cases. *Giardia* case-finding is hampered by false-negative results of microscopic examination of fecal material,[15] the diagnostic method used in this investigation. Alternative methods including duodenal aspirates or biopsy examination and in vitro culture also show false-negative results and the complexity of methods precluded their use in this investigation.[16] Although heightened surveillance and screening during the outbreaks probably identified a majority of cases, only selected groups of persons had stool examinations and some cases may have gone undetected; persons with undetected cases may have continued to transmit *G. lamblia*. Also, transmission possibly occurred prior to institution of drug therapy for cases. Although drug treatment was instituted in >90 per cent of identified cases, completion of two test-of-cure follow-up stool examinations was achieved for only 52 per cent of cases. Those without post-treatment stool examinations would be expected to have a cure rate similar to the >90 per cent cure rate for tested persons, but some of these persons may have been still capable of transmitting infection. Several cases required retreatment due to continued shedding of *G. lamblia* cysts; transmission may have occurred during this interval of cyst shedding.

By the onset of outbreak B, 58 per cent of the attendees <36 months old were new to the day care facility and by the onset of outbreak C, 33 per cent of attendees <36 months old were new to the center. No systematic assessment employing the collection of multiple stool specimens has been made to determine the prevalence of *G. lamblia* infection in the Dane County child population, but using an estimate of 5 per cent prevalence derived from a review of *G. lamblia* surveys,[17] at least one or two of the entering children would be expected to have a *Giardia* infection. During the interval of the three outbreaks, four staff terminated and four new staff were hired (a 24 per cent turnover of staff). This is consistent with the approximately 30 per cent annual turnover rate among the day care employees observed in Dane County, Wisconsin (personal communication, Lynn Mussallem, RN, Madison City Health Department). Although staff turnover may not be as important in the introduction of *Giardia* infection and the continued education provided throughout the interval of outbreaks should have minimized the effect of staff turnover on the control measures, it is possible that the efforts toward consistent hand washing and environmental control practices were hindered by high staff turnover rates.

Attack rates were higher for children who had previous *Giardia* infections. Additionally, attack rates in the children were high in each of the outbreaks but decreased among the staff from outbreak to outbreak. One possible explanation for this observation is that previously positive children may have continued to harbor *G. lamblia* cysts despite test-of-cure negative stools. Alternatively, children with previous *G. lamblia* infection may have behavior patterns which increase their exposure to the organism. Acquired immunity to *Giardia* infection has been suggested in adult human populations[18–20] and there is experimental evidence of acquired immunity in mice.[21,22] It is possible that immunity is not established in young children or that immune response is blunted by early drug therapy, but these factors could not be assessed in our investigation. Conceivably, a child's behavior which fosters *Giardia* transmission puts that child at increased risk for continual exposure and, despite even partial immunity, recurrent infection may be common in these individuals.

The most effective means for control of *Giardia* transmission in the day care setting is still debated. Some investigators have suggested treating all day care-associated cases of giardiasis regardless of symptoms because of the possibility of transmission of *G. lamblia* by asymptomatic cyst-passers[2,11] while others have encouraged treatment only in symptomatic children.[5,10] During these three outbreaks in Wisconsin, 93 per cent of *Giardia*-infected children and staff and all 10 households contact cases were pharmacologically treated regardless of symptoms. Day care center children with previous *Giardia* infection may be at increased risk for re-infection or recrudescence of old infection and should receive special follow-up. Management policies which minimize high turnover rates among employees and attendees may be beneficial in the control of *G. lamblia* transmission and possibly other infections. A carefully conceived plan for environmental preventive measures and drug therapy of symptomatic children, symptomatic household contacts, and possibly certain asymptomatic *G. lamblia* cyst passers should be established in child day care facilities. Our findings suggest that, given the ubiquity of the *G. lamblia* organism and because of the time commitment required for case identification/treatment/follow-up and the potential for drug treatment failures, hygienic control measures should receive increased emphasis in day care settings. However, clinicians, public health workers, and day care personnel can expect day care center outbreaks of giardiasis to recur.

ACKNOWLEDGMENTS

The nursing staff of the Madison City Health Department (Lynn Mussallem, Susan Haag, Diane McHugh) and the directors of involved day care centers provided invaluable support in the investigation.

National Conference on HBP Control, May 6–9 at Disney World Village

The National Conference on High Blood Pressure Control, to be held May 6–9, 1989 at the Hilton Hotel, Walt Disney World Village in Florida, will address many of today's concerns for HBP control in special populations. High blood pressure continues to be the major cause of stroke and kidney failure and a principal contributor to heart attack deaths—costing the nation hundreds of thousands of lives and billions of dollars each year.

This year's conference is sponsored by the National High Blood Pressure Education Program Coordinating Committee, in cooperation with the International Society on Hypertension in Blacks. Plenary sessions will highlight sodium, potassium, and calcium; metabolic effects and their influence on the selection of antihypertensive drugs; nonpharmacological issues and Black hypertensives; and management of hypertensive athletes. Other sessions will focus on new drugs, special topics for clinicians, and equipment calibration.

Special events include a poolside brunch, activities to celebrate National Church High Blood Pressure, and free time to visit Disney World Attractions. For more information, contact:

A New Epidemiologic and Laboratory Classification System for Paralytic Poliomyelitis Cases

ROLAND W. SUTTER, MD, MPH & TM, EDWARD W. BRINK, MD, STEPHEN L. COCHI, MD, OLEN M. KEW, PhD, WALTER A. ORENSTEIN, MD, ROBIN J. BIELLIK, DrPH, AND ALAN R. HINMAN, MD

Abstract: An epidemiologic classification of paralytic poliomyelitis cases (ECPPC) has been in use in the United States since 1976. In 1985, this classification system was reviewed because of recent changes in the epidemiology of paralytic poliomyelitis and improved laboratory capability to definitively characterize poliovirus strains. An alternative classification system was devised, the epidemiologic and laboratory classification of paralytic polio cases (ELCPPC), that incorporated virus isolation and strain characterization with epidemiologic information. Reported paralytic poliomyelitis cases for 1980–86 were classified by both the ECPPC and the ELCPPC classification systems. The new ELCPPC system classified 91 per cent of the reported cases as vaccine-associated, while the ECPPC system classified only 71 per cent of the reported cases as vaccine-associated. The proposed classification system provides more specific and useful information particularly concerning vaccine-associated paralytic poliomyelitis. (*Am J Public Health* 1989; 79:495–498.)

Introduction

Poliomyelitis control efforts have been very successful in the United States. Paralytic poliomyelitis cases declined from approximately 16,000 per year in the early 1950s, the immediate pre-vaccine era, to an annual average of less than 10 cases during 1980–86.[1,2]

A system for classification of paralytic poliomyelitis cases known as "epidemiologic classification of paralytic poliomyelitis cases" (ECPPC) has been in use since 1976.[3] Both the last epidemic of poliomyelitis and the last known case of endemic paralytic poliomyelitis due to wild poliovirus in the United States occurred in 1979.[4] Approximately one case of imported paralytic poliomyelitis is reported annually. Oral polio vaccine (OPV), in wide use since 1960, has been associated with a small number of cases of paralytic poliomyelitis annually among vaccine recipients and their susceptible contacts.[5,6] The overall risk of vaccine-associated paralytic poliomyelitis for the period 1973–84 was estimated as one case of paralytic poliomyelitis per 2.6 million doses of OPV distributed.[6] With the elimination of epidemic and endemic cases of paralytic poliomyelitis and only one imported case per year, vaccine-associated paralytic poliomyelitis has become more important. Poliovirus isolates were first reliably identified at the Centers for Disease Control (CDC) by their antigenic properties, using specific polyclonal antibodies,[7] an approach further refined by the use of cross-adsorbed antisera described by van Wezel.[8] While the specificity of antigenic characterization has improved with the development of panels of neutralizing monoclonal antibodies,[9–12] polioviruses are most definitively identified by molecular methods such as oligonucleotide fingerprinting or partial genomic sequencing,[13,14] which measure the extent of genetic sequence relationship among isolates. Molecular characterizations, used at CDC since 1980, have generally (> 90 per cent) confirmed identifications made on the basis of antigenic properties. Confirmation of suspected paralytic poliomyelitis cases depends on medical, epidemiological, and laboratory data. The isolation of polioviruses in stool specimens of patients with suspected poliomyelitis contributes to the decision-making process but does not constitute proof of a causal association of such viruses with paralytic poliomyelitis.

We describe a new classification system for reported paralytic poliomyelitis cases which integrates epidemiologic criteria, virus isolation, and strain characterization results, and then compare it with the existing classification system by applying both systems to reported paralytic poliomyelitis cases in the United States for the period 1980–86.

ECPPC Classification System

The ECPPC classification system distributes all cases into one of four categories: epidemic, endemic, imported, or immune deficient (Table 1). The system classifies cases based on epidemiologic information alone. When it was established, laboratory tests were not available for definitively differentiating between strains of vaccine-like and wild polioviruses.

ELCPPC Classification System

In 1985, expert consultants were asked by CDC to review the applicability of the ECPPC system because of

TABLE 1—Epidemiologic Classification of Paralytic Poliomyelitis Cases (ECPPC): United States, 1980 through 1986

	Categories	Number of Cases
I.	EPIDEMIC	
	A. Oral Polio Vaccine (OPV) not received from 4–30 days before onset of illness	0
	B. OPV received from 4–30 days before onset of illness	0
II.	ENDEMIC	
	A. No history of receiving OPV or of contact with an OPV recipient as defined in B and C below	6
	B. OPV received from 4–30 days before onset of illness	23
	C. Onset of illness 4–60 days after OPV was fed to a recipient in contact with the patient *and* contact occurred within 30 days before onset of illness	
	1. Household contact—vaccinee and patient regularly share the same home for sleeping	14
	2. Community contact or non-household contact	10

TABLE 2—Epidemiologic and Laboratory Classification of Paralytic Poliomyelitis Cases (ELCPPC): United States, 1980 through 1986

Categories	Number of Cases
I. SPORADIC	
A case of paralytic poliomyelitis not linked epidemiologically to another case of paralytic poliomyelitis	
A. Wild virus poliomyelitis. Virus characterized as wild virus	0
B. Vaccine-associated poliomyelitis	
1. Recipient—OPV was received 4 to 30 days before onset of illness	
a. Virus characterized as vaccine-related	16
b. Virus not isolated or not characterized	7
2. Contact—Illness onset was 4 to 75 days after OPV was fed to a recipient in contact with patient and contact occurred within 30 days before onset of illness	
a. Household—vaccinee and patient regularly share the same household for sleeping	
i. Virus characterized as vaccine-related	11
ii. Virus not isolated or not characterized	5
b. Non-household	
i. Virus characterized as vaccine-related	6
ii. Virus not isolated or not characterized	3
3. Community—No history of receiving OPV or of contact with an OPV recipient, as defined in 1 and 2, and virus isolated and characterized as vaccine-related	4
C. Poliomyelitis with no history of receiving OPV or of contact with an OPV recipient, as defined in B1 and B2, and virus not isolated or not characterized	1
II. EPIDEMIC	
A case of paralytic poliomyelitis linked epidemiologically to another case of paralytic poliomyelitis	
A. Not a recipient of OPV	
1. Virus characterized as wild virus	0
2. Virus characterized as vaccine-related	0
3. Virus not isolated or not characterized	0
B. OPV recipient—OPV received 4 to 30 days before onset of illness	
1. Virus characterized as wild virus	0
2. Virus characterized as vaccine-related	0
3. Virus not isolated or not characterized	0
III. IMMUNOLOGICALLY ABNORMAL	
Proven or presumed	
A. Wild virus poliomyelitis—Virus characterized as wild virus	0
B. Vaccine-associated poliomyelitis	
1. Recipient—OPV was received 4 to 30 days before onset of illness	
a. Virus characterized as vaccine-related	5
b. Virus not isolated or not characterized	0
2. Contact—Illness onset was 4 to 75 days after OPV was fed to a recipient in contact with patient and contact occurred within 30 days before onset of illness	
a. Household—vaccinee and patient regularly share the same household for sleeping	
i. Virus characterized as vaccine-related	1
ii. Virus not isolated or not characterized	0
b. Non-household	
i. Virus characterized as vaccine-related	1
ii. Virus not isolated or not characterized	0
3. Community—No history of receiving OPV or of contact with an OPV recipient, as defined in 1 and 2, and virus isolated and characterized as vaccine-related	1
C. Poliomyelitis with no history of receiving OPV or of contact with an OPV recipient, as defined in B1 and B2, and virus not isolated or not characterized	0
IV. IMPORTED	
Poliomyelitis in a person (US resident or other) who has entered the United States	
A. Virus characterized as wild virus	
1. Onset of illness within 30 days before entry	2
2. Onset of illness within 30 days after entry	1
B. Virus characterized as vaccine-related	
1. Onset of illness within 30 days before entry	0
2. Onset of illness within 30 days after entry	0
C. Indeterminate—Virus not isolated or characterized	
1. Onset of illness within 30 days before entry	1
2. Onset of illness within 30 days after entry	1
TOTAL	66

recent changes in the epidemiology of paralytic poliomyelitis in the United States and the improved laboratory capability since 1980 to definitively characterize poliovirus strains. The consultants were requested to:

- provide revisions of the system or an alternative if in their view the current classification system was no longer adequate;
- apply any revised or new system to cases of poliomyelitis with onset of illness from 1980–84 that met the CDC Paralytic Poliomyelitis case definition*;
- classify the same cases of poliomyelitis by the older ECPPC system.

For reported cases of paralytic poliomyelitis with onset in 1985 and 1986 and for cases with onset in 1980–84 but reported after the 1985 review, personnel at CDC assigned cases to classification categories in both systems. The consultants recommended that an alternative classification system be adopted that would incorporate virus isolation and strain characterization results and epidemiological information. The system, labeled the Epidemiologic and Laboratory Classification of Paralytic Poliomyelitis Cases (ELCPPC), is presented in Table 2. Some definitions for case classification were changed: 1) a contact case has onset of illness 4–75 days (formerly 4–60 days) after OPV was fed to a recipient in contact with the case; 2) "immunologically abnormal" includes cases in persons with proven or presumed immunological abnormalities regardless of the etiology of their abnormality (primary immunodeficiency, drug-induced suppression, etc.); and 3) "imported" includes cases in persons (US residents or others) with onset within 30 days before or after entry into the United States.

Comparison between ECPPC and ELCPPC Classification Systems

A total of 66 reported cases of paralytic illness with onset during the period 1980–86 met the CDC definition for paralytic poliomyelitis; 45 cases were confirmed by expert consultants in 1985 and the remaining cases by expert reviews since then. Poliovirus isolates were available for analysis for 46 (70 per cent) of the 66 cases, and van Wezel type-specific neutralization, oligonucleotide fingerprinting, and/or genomic sequencing was done. Forty-three viruses (93 per cent) were characterized as vaccine-like and three (7 per cent) as wild. These cases were classified according to the new ELCPPC system (Table 2).

The cases also were classified according to the old system, ECPCC, using only the available epidemiologic information (Table 1). Six cases were classified into the category "endemic, not vaccine-associated." In fact, poliovirus was isolated and characterized as vaccine-like from five of these cases. No specimen was available from the sixth patient. Three of the five cases classified as imported cases had poliovirus isolated and characterized as wild. No specimens were available from the other two patients. Five of the eight immune-deficient cases had received oral polio vaccine (OPV) and two had contact with a recipient; information was insufficient on the remaining case. All eight immune-deficient cases had poliovirus isolates characterized as vaccine-like.

For the period 1980–86, 60 of the 66 reported cases of paralytic poliomyelitis in the United States were vaccine-associated either by epidemiologic and/or strain characterization; five (8 per cent) cases were imported and one case that occurred in 1980 could not be classified as vaccine-associated paralytic poliomyelitis because no specimen for isolation was available and epidemiologic information was incomplete. While the ELCPPC classified 91 per cent of the cases by epidemiological and/or laboratory characterization as vaccine-associated, only 71 per cent were classified as vaccine-associated by the ECPPC which relies on epidemiological information (Table 3).

International Application

The World Health Organization (WHO) estimates that more than 250,000 cases of paralytic poliomyelitis occur each year worldwide.[15] Control or elimination of the disease in developed countries using either oral or inactivated polio vaccine has generated interest in the global eradication of poliomyelitis.[16,17] Given the progress by the Expanded Program on Immunization of WHO in achieving immunization with three doses of polio vaccine of more than 50 per cent of children in many developing countries,[15] the World Health Assembly adopted the goal in May 1988 of global eradication of poliomyelitis by the year 2000.[18] The WHO Region of the Americas, through the Pan American Health Organization (PAHO), established a target for elimination of indigenous poliomyelitis by the end of 1990, while the WHO European and Western Pacific Regions have set targets for elimination by 1995. Global eradication of poliomyelitis is feasible by achievement and maintenance of high immunization levels, effective surveillance to detect all new cases, and a rapid vigorous response to the occurrence of new cases.[19] To monitor these efforts, laboratory systems have been developed that identify which type(s) of polioviruses are circulating in a country or region, and to distinguish vaccine-virus from wild-virus,[14] but these methods need to be made more widely available. Countries without current access to such a laboratory system will face delay in being able to fully utilize the ELCPPC. However, even in the absence of such laboratory support, paralytic polio cases can be classified within the distinct epidemiologic categories of the ELCPPC.

TABLE 3—Comparison of Vaccine-Associated Paralytic Poliomyelitis Cases by Classification Category in the ECPPC and ELCPPC Systems

Category	System	Number of cases	
		Total	Vaccine-Associated (%)
Endemic*	ECPPC	53	47 (89%)
Sporadic*	ELCPPC	53	52 (98%)
Immunodeficient#	ECPPC	8	0** (0%)
Immunologically Abnormal#	ELCPPC	8	8 (100%)
Epidemic - Imported	ECPPC	5	0 (0%)
	ELCPPC	5	0 (0%)
All Categories	ECPPC	66	47 (71%)
	ELCPPC	66	60 (91%)

#Comparable categories
*Comparable categories
**Classification not available under ECPPC System

*A patient must have had paralysis clinically and epidemiologically compatible with poliomyelitis and, at 60 days after onset of symptoms, had a residual neurological deficit, had died, or had no information available on neurologic residua (This classification was formerly known as the Best Available Paralytic Poliomyelitis Case Count (BAPPCC) case definition).

Conclusion

Advances in methods to characterize strains of poliovirus as vaccine-like or wild provided the stimulus to improve upon the ECPPC system which relies entirely on epidemiological information. In addition, the epidemiology of poliomyelitis in the United States changed substantially. Epidemic and endemic wild poliomyelitis disease no longer exists in the United States, and vaccine-associated disease is the most frequent form of paralytic poliomyelitis. Since 1980 an average of only eight cases have been reported annually. The new system, ELCPPC, corrects for misclassifications in the older ECPPC system in which some cases were categorized as "endemic, not vaccine-associated" even when laboratory confirmation of a vaccine-virus infection was available.

While the ELCPPC format is at first glance somewhat complex, the greater descriptive accuracy of each category and subcategory provides more specific and useful information particularly concerning vaccine-associated disease. Information on the relative occurrence of wild-virus and vaccine-associated cases within each epidemiologic category can be obtained rapidly from this tabular format.

As current worldwide efforts to immunize children against polio are expanded and the effectiveness of these efforts is documented by a sustained decrease in polio cases, the ELCPPC system will become useful as a standardized tool to track the success of these programs and eventually to help in certifying countries or regions as free of wild poliomyelitis.

The Relationship between Women's Attitudes about Condoms and Their Use: Implications for Condom Promotion Programs

RONALD O. VALDISERRI, MD, MPH, VINCENT C. ARENA, PHD, DONNA PROCTOR, RN, MPA, AND FRANK A. BONATI, DRPH

Abstract: A survey of 759 women attending contraceptive care clinics revealed that a majority of women endorsed condom use as an important way to reduce the spread of AIDS (acquired immunodeficiency syndrome); 82 per cent reported past use of condoms, but only 14 per cent reported using condoms in addition to another form of contraception to prevent infection with sexually transmitted pathogens, including HIV (human immunodeficiency virus). Acceptance of condom advertisement, perceived male and peer acceptance of condoms, and the effect of condom use on the enjoyment of sexual intercourse predicted condom use. (*Am J Public Health* 1989; 79: 499–501.)

Introduction

In a recent mailing to American citizens on the subject of AIDS (acquired immunodeficiency syndrome), readers were advised that "not having sex," or having sex with "one mutually faithful, uninfected partner" are "safe behaviors" that will protect one from AIDS.[1] For individuals falling outside of these categorizations, condom-protected intercourse is the next best option. However, merely warning persons about the dangers of sexually transmitted HIV (human immunodeficiency virus) infection and urging the use of condoms may not result in their widespread adoption. We conducted a survey of sexually active women to assess their knowledge of, attitudes about, and use of condoms.

Methods

During the months of September and October 1987, 800 questionnaires pertaining to condom use knowledge, attitudes, and practice were distributed to clients at eight contraceptive care clinics (100 consecutive clients per site) in urban, suburban, small town, and college campus locations in southwestern Pennsylvania. The questionnaire consisted of 10 true/false questions, 12 attitudinal items, questions about past and current condom use, and several questions relating to the demographic characteristics of the applicants.

Categorial variables were analyzed using the chi-square test. Multiple linear logistic regression, using maximum likelihood estimation, was performed to simultaneously assess the association of co-variables with the dependent outcome of current condom use.[2]

Results

Seven hundred fifty-nine completed surveys were returned for analysis. Over half of the participants were between the ages of 19 and 25, 84 per cent were White, 41 per cent had at least a high school diploma, 15 per cent were married, and 15 per cent were living with a male partner to whom they were not married. 86 per cent reported a single sexual partner, 6 per cent had more than one sexual partner, and 8 per cent were not sexually active at the time of the survey.

Eighty-two per cent of the women reported that they had used condoms with a male sexual partner at least once in the past; 74 per cent reported that this was for "birth control," 3 per cent reported it was "to prevent VD," and 23 per cent said "for both purposes." Twenty-one per cent of the women reported they were currently using condoms with or without contraceptive foam for "birth control" and 14 per cent were currently using condoms and another contraceptive "to prevent VD."

Although the results from the true/false questions revealed a relatively high general level of knowledge about condoms and HIV transmission, a number of inaccuracies were noted, including: 26 per cent believed that vaseline "is the best lubricant to use with condoms"; 21 per cent believed that withdrawing the penis before ejaculation "is as safe" as using a condom in terms of preventing AIDS; 12 per cent believed that the virus which causes AIDS cannot be found in both male and female genital secretions; and 9 per cent thought a woman "could not get AIDS" from a male sexual partner unless she had anal intercourse with him.

Table 1 outlines the women's responses to the attitudinal items as a composite and then dichotomized between "users" (women who report current use of condoms with or without foam as a contraceptive) and "non-users." The majority endorsed condoms as an important way to prevent the spread of AIDS, especially with a new sexual partner, although 37 per cent expressed uncertainty of their ability to initiate use, and 22 per cent believed they would be "too embarrassed" to purchase condoms in a drug store. Non-users were more likely to feel that most men do not like using condoms, that condom-protected intercourse would not be enjoyable, were less likely to report peer acceptance of condoms, and more likely to be unsure about feeling "insulted" if a partner wanted to use a condom.

TABLE 1—Attitudes Pertaining to Condom Use: Per Cent of Total Cohort and Condom Users versus Non-users

Women's Responses		% Agree	% Disagree	% Not sure
Most men do not like using condoms		80.5	7.4	12.1
	User Non	73.5 82.3	13.2 5.8	13.2 11.8
I would be insulted if my male partner wanted to use a condom while he was having sex with me		5.2	86.1	8.7
	User Non	6.0 5.0	90.7 84.9	3.3 10.1
If I were planning on having sex with a man I didn't know, I would ask him to use a condom		87	1.4	11.6
	User Non	91.4 85.9	7.1 6	7.9 12.6
I wouldn't know how to bring up the subject of condoms with a new sexual partner		14.9	63.2	21.9
	User Non	14.6 14.9	65.6 62.6	19.9 22.5
Most of the women I know think that using condoms with a new sexual partner is a good idea		77.2	6.1	16.6
	User Non	84.8 75.3	5.3 6.3	9.9 18.4
I would be too embarrassed to buy condoms at a drug store		21.8	62.8	15.4
	User Non	20.5 22.1	62.9 62.8	16.6 15.1
I worry a lot about getting AIDS from a new sexual partner		69.9	17.7	12.3
	User Non	69.8 70.0	18.8 17.5	11.4 12.6
I think that condoms should be advertised on television as a way to prevent the transmission of AIDS		84.0	5.2	10.8
	User Non	88.7 82.8	1.3 6.2	10.0 11.0
I think I would feel "dirty" if a man wanted to use condoms with me		2.5	93.5	4.1
	User Non	1.3 2.7	95.4 93.0	3.3 4.3
I think that condoms are an important way to reduce the spread of AIDS		95.6	1.2	3.1
	User Non	96.0 95.5	7.1 4	3.3 3.1
I don't think I would enjoy intercourse if my partner used condoms		12.7	70.3	17.0
	User Non	4.6 14.8	88.7 65.5	6.6 19.7
Even if I were using some other method of birth control, I think that I would still use a condom with a new sexual partner to prevent myself from becoming infected with VD (including AIDS)		81.2	3.7	15.1
	User Non	84.0 80.5	3.3 3.8	12.7 15.7

Differences by race in response to the knowledge questions were negligible (data available upon request to authors).

Responses to nine of the 12 attitudinal items differed by race (data available upon request to authors). Black respondents (n=117) were more likely to worry about AIDS, to endorse the use of condoms, especially with a new sexual partner, to report peer acceptance of condoms, and were less likely to feel unsure about initiating condom use or to be embarrassed about purchasing condoms.

Forward stepwise multiple logistic regressions were used to investigate the association between the previously described variables and condom use (Table 2). The first model contained demographic, knowledge, and attitudinal variables; the second contained only attitudinal variables. In both instances, attitudes alone were predictive of condom use.

Discussion

Among men, a variety of reasons have been recorded for underutilization of condoms, including: lack of ready access; failure to plan for sexual intercourse; the use of alcohol and/or drugs prior to sex; beliefs that condoms impair sexual pleasure; the belief that condoms would be offensive to one's partner; and the belief that condoms are unnatural or immoral.[5-7] Many of these same barriers no doubt hold true for women as well.[8]

Our finding that attitudes about condoms were the only independent variables capable of predicting their use suggests that condom promotion programs targeted to women must attempt to alter these attitudes. To that end, programs

c) "I don't think I would enjoy intercourse if my partner used condoms."
d) "Most of the women I know think that using condoms with a new sexual partner is a good idea."

should include skills-training sessions which incorporate role playing and small group discussion. Experienced peers may be especially effective in addressing the perception that condoms interfere with sexual pleasure, since condom acceptance is known to increase with increased experience.[9]

Condom promotion programs must also be flexible enough to meet individual needs. There may be significantly different perceptions about condom use among women from different racial/ethnic backgrounds.

The observed discrepancy between the widespread endorsement of condoms and the frequency of reported use probably reflects the fact that many of the women we surveyed do not perceive themselves to be at risk for HIV infection,[10] because most reported only a single sexual partner. Therefore, the ability to generalize these findings to women who belong to targeted "risk groups" is limited. Nevertheless, we believe that the identification of generic barriers to women's use of condoms for contraception does provide direction for the development of condom promotion programs which can then be applied to other populations, especially those at increased risk of HIV infection.

ACKNOWLEDGMENTS

This research was supported by the Family Health Council of Western Pennsylvania and by the Pathology Education and Research Foundation of the University of Pittsburgh. The authors would like to thank the staff and clients of the Family Planning Council of Western Pennsylvania for their support of and participation in this survey. We also would like to thank Dr. Edmund Ricci for technical assistance. This work was presented at the First International Symposium on Information and Education on AIDS, in Ixtapa, Mexico, October 16–20, 1988.

Sexual Behavior Changes and HIV Antibody in a Cohort of New York City Gay Men

JOHN L. MARTIN, PHD, MPH, MARC A. GARCIA, MA, AND SARA T. BEATRICE, PHD

Abstract: A sample of 357 gay/bisexual men, ages 20 to 65, were interviewed in 1985 regarding their sexual patterns over the course of the AIDS (acquired immunodeficiency syndrome) epidemic. Within four months after the interview, men were tested for antibody to HIV (human immunodeficiency virus) and 36 per cent were found positive. Cessation of receptive anal intercourse was associated with HIV negative antibody status, (OR > 3.0). Reducing the number of sexual partners, becoming monogamous, or eliminating other forms of sexual contact were not related to risk of HIV. (*Am J Public Health* 1989; 79:501–503.)

Introduction

Without a vaccine against human immunodeficiency virus (HIV) or efficacious treatments for HIV-related illnesses, the primary means available for controlling the AIDS (acquired immunodeficiency syndrome) epidemic is through education and the self-regulation of transmission risk behavior. For gay/bisexual men, two main types of behavior change have been recommended[1–3]: reduce the number of different sexual partners, and eliminate the exchange of body fluids during sexual encounters. Although gay men in San Francisco and New York City have substantially changed their sexual behavior patterns to conform with these recommendations,[4–7] persistence of high-risk sexual activity continues among a minority of these well informed cohorts.[6] In addition, high rates of risk-taking behavior have been reported among gay men in areas with low AIDS incidence.[8,9]

While it is well established that unprotected anal intercourse is the primary sexual behavior associated with HIV infection,[10–15] evaluation of the usefulness of actual *changes* in sexual behavior in preventing HIV infection among those initially at high risk is less common.[16] Thus, we undertook this study to determine the extent to which changes in sexual behavior occurring after the onset of the AIDS epidemic altered the likelihood of HIV infection among gay men.

Methods

This analysis is based on 357 of the 746 gay men recruited to study the impact of AIDS on the New York City gay community.[7] Respondents were primarily White (87 per cent), college educated (81 per cent), with an average age of 36 (SD = 7.4). No differences were found between the groups who agreed to and who refused testing (but agreed to be interviewed) on any sexual behavior variable, including numbers of partners or frequency of anal intercourse. (See Martin, *et al.*[17] for a detailed discussion of this sample.)

HIV Antibody Serology

HIV testing was performed by the New York City Department of Health. Two HIV-ELISA (enzyme-linked

A Comparison of Acquired Immunodeficiency Syndrome and Kaposi's Sarcoma Incidence Rates, Atlanta, 1983–86

Wong-Ho Chow, PhD, Jonathan M. Liff, PhD, Raymond S. Greenberg, MD, PhD, and Brian O. Williams, MD

Abstract: Recent temporal trends in incidence rates for acquired immunodeficiency syndrome (AIDS) and Kaposi's sarcoma were compared in metropolitan Atlanta, Georgia. From 1983 through 1986 the age-adjusted incidence rate of Kaposi's sarcoma among White males ages 25–49 increased 11-fold (2.2–24.4/100,000 person years). The annual incidence rate of AIDS increased ten-fold (11.3–113.3/100,000). These findings do not support earlier reports that the proportion of AIDS patients with Kaposi's sarcoma has decreased over time. (*Am J Public Health* 1989; 79:503–505.)

Introduction

In 1981, the first cases of acquired immunodeficiency syndrome (AIDS) in the United States were recognized among young homosexual males with Kaposi's sarcoma or *Pneumocystis carinii* pneumonia and no other known cause of immunodeficiency.[1,2] The proportion of reported AIDS cases with Kaposi's sarcoma has declined over time in the United States.[3,4] It has been suggested that some portion of this decreasing occurrence of AIDS-related Kaposi's sarcoma may be due to reduced exposure to cofactors of Kaposi's sarcoma,[4,5] such as the use of butyl nitrite among homosexual males.[6]

Few estimates of the incidence of AIDS have been reported because of difficulties in determining the size of the populations at risk.[2,6] Estimates of temporal trends in the occurrence of AIDS usually are based solely on changes in the total number of reported cases.[2,7,8] In contrast, trends over time in the incidence of Kaposi's sarcoma have been reported for the years prior to the onset of the current AIDS epidemic.[9] In the present study, recent temporal trends in incidence rates for both AIDS and Kaposi's sarcoma are reported and compared for young White males in metropolitan Atlanta, an area that has a relatively high incidence of AIDS.[10]

Methods

The data on AIDS incidence presented in this report were collected by the AIDS Surveillance Unit of the Georgia Department of Human Resources. AIDS became a reportable disease by law in Georgia in January 1984. For each case, the diagnosing physician is required to complete a standard reporting form with demographic and clinical information. AIDS cases diagnosed prior to 1984 were identified retrospectively by active surveillance methods including: review of tumor registry reports for Kaposi's sarcoma cases under 60 years of age at diagnosis; survey of physicians by letter and telephone; review of death certificates from Georgia; and review of requests received by the Centers for Disease Control (CDC) for pentamidine isethionate, a medication used for the treatment of *P. carinii* pneumonia[1,2,11] for which CDC has been the sole supplier until recently.[11]

Since first published in September 1982,[12] the AIDS definition for surveillance purposes has undergone minor revisions. Because the current study included cases diagnosed only through 1986, the latest revision would have had minimal impact on case identification.

The data on Kaposi's sarcoma presented in this report were collected by the Georgia Center for Cancer Statistics, a population-based cancer registry affiliated with the Surveillance, Epidemiology and End Results (SEER) Program of the National Cancer Institute.[13] This registry has been responsible for obtaining information on all cancers diagnosed among residents of metropolitan Atlanta since 1975.[14]

The primary method of cancer patient identification was through review of pathology reports and discharge diagnoses at the hospitals, clinics, and freestanding pathology laboratories in and around metropolitan Atlanta. Overall, less than 1 per cent of cases reported to the registry were identified from death certificates only. The abstracted demographic and clinical information was transcribed onto standard data collection forms, edited, and coded according to the guidelines of the SEER Program.[13]

TABLE 1—Demographic Characteristics of AIDS and Kaposi's Sarcoma Patients Diagnosed between 1983 and 1986, Metropolitan Atlanta, Georgia

Characteristics	Category	All AIDS n	All AIDS (%)*	Kaposi's Sarcoma n	Kaposi's Sarcoma (%)*
Race	White	377	74.8	74	85.1
	Black	119	23.6	10	11.5
	Other**	8	1.6	3	3.4
Sex	Male	490	97.2	86	98.9
	Female	14	2.8	1	1.1
Age at Diagnosis (years)	<25	30	6.0	3	3.2
	25–29	102	20.2	21	22.3
	30–34	137	27.2	20	21.3
	35–39	127	25.2	15	16.0
	40–44	61	12.1	17	18.1
	45–49	28	5.6	8	8.5
	50–54	10	2.0	1	1.1
	55–59	9	1.8	2	2.1
County of Residence	Fulton	364	72.2	67	77.0
	DeKalb	89	17.7	14	16.1
	Other†	51	10.1	6	6.9

*Numbers in parentheses are percentages of all patients within a disease classification
**Includes 2 Kaposi's sarcoma cases with unknown race; all AIDS cases under this category were Hispanic
†Includes 4 AIDS cases with unknown county of residence

For the current analyses, information about all histologically confirmed Kaposi's sarcomas newly diagnosed between January 1, 1983 and December 31, 1986 among persons under 60 years of age was extracted from the database of the cancer registry. Similarly, information about all residents under 60 years of age with a new diagnosis of AIDS during the same time period was extracted from the database of the AIDS Surveillance Unit. No linkage of information about individuals reported to the cancer registry and the AIDS Surveillance Unit was attempted because of confidentiality requirements for each database. Race and age-specific incidence rates of Kaposi's sarcoma and AIDS were computed separately, using as denominators estimates derived by the US Bureau of the Census and the National Cancer Institute for the years 1983–86. The incidence rates for each calendar year were age-adjusted to the 1970 US population by the direct method, and approximate 95 per cent confidence intervals were calculated.[15]

Results

This study population included 504 patients with AIDS and 87 patients with Kaposi's sarcoma. A slightly higher proportion of Kaposi's sarcoma patients were White (85.1 per cent) compared with all AIDS patients (74.8 per cent). The distributions by sex, age, and county of residence were similar for these two samples of patients, however (Table 1). The median age for both groups of patients was 34 years, with the age ranging from 1 to 59 years for AIDS cases and from 19 to 58 years for Kaposi's sarcoma cases.

The remaining analyses focused only on White males between the ages of 25 and 49 years, who lived in Fulton or DeKalb counties; among them, the peak incidence rate of AIDS during 1983–86 (92.5 per 100,000) occurred among those ages 35–39, while that of Kaposi's sarcoma (19.2 per 100,000) peaked at ages 40–44 years.

Between 1983 and 1986, the age-adjusted incidence rate of Kaposi's sarcoma increased 11-fold, from 2.2 to 24.4 cases per 100,000 person years (Table 2), and there was a 10-fold rise in the annual incidence rate of AIDS, from 11.3 to 113.3. The incidence rate ratios of Kaposi's sarcoma and AIDS varied from 0.19 to 0.29, with no consistent trend over time (Table 2).

Discussion

In contrast to previous reports,[3,4] we found parallel increases in the incidence of AIDS and Kaposi's sarcoma among White males ages 25–49 years in Atlanta. If AIDS cases had been underreported in metropolitan Atlanta to a greater extent than in other cities, and if the underreporting had increased each year, the parallel increase we observed could have occurred even if the true ratio of Kaposi's sarcoma to AIDS cases had been decreasing. Data from CDC,[16] however, show that the proportional increase in the number of AIDS cases in Atlanta between 1984 and 1986 was even greater than in the nation as a whole. In addition, there was no abrupt increase in the incidence of reported AIDS cases in 1984, the year during which AIDS became reportable by law in Georgia, suggesting that the reporting of AIDS in Atlanta was fairly complete even prior to 1984. Previous studies in other settings also have found that the reporting of AIDS is quite complete in general.[17,18]

As conditions other than Kaposi's sarcoma and *P. carinii* pneumonia have been accepted as diagnostic evidence of AIDS, the proportion of cases presenting with Kaposi's sarcoma might be expected to decrease over time; we found that this proportion decreased from 26.3 per cent in 1983 to 19.0 per cent in 1986 among White males. Our data, based on separate data sources include Kaposi's sarcomas presenting subsequent to the initial diagnoses of AIDS, thus more clearly indicating the proportion of AIDS patients with

TABLE 2—Annual Numbers of Cases, Age-Adjusted Incidence Rates, and Rate Ratios of Kaposi's Sarcoma and AIDS among White Males Ages 25–49 in Fulton and DeKalb Counties, Metropolitan Atlanta, 1983–86

Group		Year of Diagnosis 1983	1984	1985	1986
Kaposi's Sarcoma	Number of cases	3	12	20	31
	Age-adjusted incidence rate*	2.2	8.5	16.7	24.4
	(95% CI)	(0.0, 4.7)	(3.6, 13.3)	(9.1, 24.4)	(15.5, 33.3)

	Age-adjusted incidence rate*	11.3	32.4	79.3	113.3
	(95% CI)	(5.7, 16.8)	(22.3, 42.4)	(63.7, 94.9)	(94.5, 132.1)
	Ratio of Kaposi's sarcoma: AIDS	0.19	0.29	0.19	0.21
	(95% CI)	(0.06, 0.56)	(0.16, 0.52)	(0.12, 0.29)	(0.15, 0.30)

*per 100,000 person years

Kaposi's sarcoma. Since the trend analysis was restricted to White men ages 25–49, it is highly likely that the registered patients with Kaposi's sarcoma also had AIDS.

When cases from other demographic subgroups (i.e., females and Blacks) were included in the analysis, the ratio of Kaposi's sarcoma to AIDS decreased somewhat in the later two years, from 0.19 in 1983 to 0.16 in 1986. The occurrence of Kaposi's sarcoma and AIDS in these other demographic subgroups, however, was too small and too recent to permit the identification of any meaningful associations.

The findings of this study suggest that the proportion of AIDS patients with concomitant Kaposi's sarcoma in young White males has not changed over time. Since these results differ from those in earlier reports, further analyses in other populations are warranted.

ACKNOWLEDGMENTS

The authors express their appreciation to the staff of the Georgia Department of Human Resources and the Georgia Center for Cancer Statistics who collected, coded, edited, and processed these data, and to the hospitals and physicians who provided information on patients for this analytic research. The Hawaii Chlamydia Network Project: A Successful Program Incorporating Close Intra-agency Cooperation

ALAN R. KATZ, MD, MPH

Abstract: The Hawaii State Department of Health's Chlamydia Network Project screened 272 asymptomatic females for chlamydia; 20 (7.4 per cent) were found to be positive. When interviewed, 75 per cent (15/20) of the cases gave information such that their sexual partner(s) could be located. Ninety per cent (14/16) of the locatable partners were brought to examination within seven days. Keys to success were the training of family planning clinic staff in STD (sexually transmitted disease) control methods, and close intra-agency cooperation. (*Am J Public Health* 1989; 79:505–507.)

Introduction

In October 1986, the Hawaii State Department of Health began a Chlamydia Network Project. The purposes of this project were to:

- Ascertain the prevalence of clinically inapparent chlamydial infections in female family planning patients;
- Develop screening protocols for chlamydia in all state-subsidized family planning clinics; and
- Develop a "network" between the Office of Family Planning and the Sexually Transmitted Disease (STD) Control Program in order to ensure all screen positive female clients and their locatable sex partners are brought to treatment in a timely manner.

Methods

The five major state-subsidized family planning clinics on the island of Oahu were involved. A total of 272 asymptomatic women were screened by obtaining a weighted sample from each of the participating clinics between December 1986 and April 1987. Eligibility criteria included any female having one or more of the following high-risk factors:[1–9] less than 25 years old; single; more than one sexual partner in the preceding 60 days; past history of a sexually transmitted disease (STD); patient being seen for an STD or STD screen, but who otherwise would not be treated for chlamydia.

Tuberculosis Surveillance in a State Prison System

STEVEN S. SPENCER, MD, AND ARTHUR R. MORTON, DO, MPH

Abstract: After four inmates at two New Mexico prisons converted their tuberculosis skin tests, a mass screening program was carried out at all of the State's adult correctional facilities (2,240 inmates). Previously unknown converters were found with a disproportionally high per cent of converters (6.8 per cent and 6.3 per cent) and reactors (14.4 per cent and 12.2 per cent) at the first two prisons. No index cases were found. State policy has been revised to include two-stage skin testing of new inmates, annual testing thereafter, and screening of all new correctional staff. (*Am J Public Health* 1989; 79: 507–509.)

Introduction

Although tuberculosis has greatly diminished in frequency in the general population of this country in recent decades, it remains a significant problem in certain population groups: some minorities, immigrants from third world countries, patients with human immunodeficiency virus (HIV) infection, residents of nursing homes, and other institutionalized groups.[1–5] Several authors have called attention to the problem of contagious tuberculosis in jails and prisons and the need for surveillance programs.[6–10] Stead in the late 1970s[6,7] showed that tuberculosis morbidity was 6.5 times greater in Arkansas prisons than in the general population of that state.[7]

The State of New Mexico Corrections Department operates seven adult correctional facilities. Prior to August of 1986, tuberculosis screening of new inmates consisted of a single Mantoux test (5 TU, PPD—Tuberculin). Those with a reaction of 10 mm of induration or more and those who gave a history of a positive skin test were x-rayed, after which a decision was made about further investigation and prophylactic treatment.[11,12] Those with negative reactions were scheduled to have repeat skin testing every two years. The tuberculin positivity rate in 1985 was 10.5 per cent.

In September of 1986, four cases of skin test conversion while in prison came to our attention. These four men all had negative skin tests at the same prison (SNM) in 1984, and one of them had been transferred shortly thereafter to another prison in the system.

From the New Mexico Corrections Department and the New Mexico Health and Environment Department. Address reprint requests to Dr. Steven S. Spencer, Medical Director, New Mexico Corrections Department, 1422 Paseo de Peralta, Santa Fe, NM 87503. Dr. Morton is Tuberculosis Control Officer of the NM Health and Environment Department. We decided to conduct a mass screening program at SNM facility. The results obtained led us to extend the program to the other five men's facilities and to the women's prison. The screening was carried out between October 1986 and April 1987.

Methods

Medical records of all inmates were reviewed; those who had been skin tested with a 0 millimeter result in the previous three months were not retested, but are included in the data for the screening program results. Inmates with a documented reaction of 10 mm or more in the past and with a chronic cough had a chest x-ray done and three sputum specimens obtained for smear and culture. Documented reactors without a cough who had completed a full course of INH (isoniazid) received no further investigation. Reactors who had not completed a course of INH and had not had a chest x-ray in the past six months, were x-rayed at the time of the mass screening. All inmates with a documented negative PPD (purified protein derivative of tuberculin) reading prior to three months earlier were skin tested. Those with any palpable reaction of less than 10 millimeters had a second stage test applied at least one week after the first. Inmates who had not been tested at intake because they gave a history of a positive skin test were tested. All converters and newly confirmed reactors also received a chest x-ray, and sputum investigation if the x-ray was suspicious. A converter was defined as one with a significant reaction whose previous negative test was within the past two years; a reactor as one whose reaction was of more than two years or of unknown duration. The housing location of all reactors and converters was recorded.

An effort was made to screen all employees at all seven correctional facilities. Those employees who could document or give a reliable history of a previous positive skin test were not retested, but did have a chest x-ray. All others received two-stage skin testing. Chest x-rays were also ordered on all reactors and converters.

Results

Inmate Screening

Table 1 shows the distribution of reactors and converters among the inmates of the seven adult correctional facilities in the state. All inmates participated in the screening program.

The skin test positivity rate (reactors plus converters divided by total number tested) was 10.7 per cent or lower in all but two of the facilities; one prison (SNM) was the one in which converters had first been identified, and the other (CNM) was the prison to which one of the converters had been transferred.

TABLE 1—Results of Inmate Screening

Facility	Screened	Negative	Reactors		Converters		Positivity Rate (%)*
			No.	(%)	No.	(%)	
SNM	466	367	67	(14.4)	32	(6.8)	(21.2)
CNM	574	468	70	(12.2)	36	(6.3)	(18.5)
PNM	685	612	62	(9.1)	11	(1.6)	(10.7)
CCW	142	129	9	(6.3)	4	(2.9)	(9.2)
CSB	61	56	5	(8.2)	0	(0)	(8.2)
LLCC	230	214	15	(6.5)	1	(0.5)	(7.0)
RCC	82	77	2	(2.4)	3	(3.7)	(6.1)
TOTALS	2,240	1,923	230	(10.3)	87	(3.9)	(14.2)

*Positivity Rate = (No. Reactors plus No. Converters) divided by No. Screened.
SNM, CNM, and PNM are medium or maximum security facilities for men. CCW is the Correctional Center for Women, all custody levels. CSB, LLCC, and RCC are minimum security facilities for men.

No active cases were found as a result of the chest x-rays on 269 reactors and converters, and sputum examinations on 38. The converters were scattered randomly among housing units or cell blocks, giving no clues to possible location of an index case.

Forty-nine (2 per cent) of the 2,240 screened inmates had no record of a previous skin test; 118 (5 per cent had a last negative skin test over two and a half years previously. (Since data were incomplete, the true number may have been higher.) Twenty of these 118 had significant reactions in the screening program.

Employee Screening

Among the employees the level of compliance was high (Table 2) and the skin test positivity rate ranged from 6.7 to 14.5 per cent, with an overall rate of 10.5 per cent. Most of the employees had not been skin tested for many years, if ever, and were therefore classified as reactors if they had a significant reaction in the screening program. Chest x-rays were done on 120 employees. No active cases of tuberculosis were found.

Discussion

Although we had thought that there might be undiscovered contagious cases in the prison system, there are other possible explanations for the skin test conversions. These include the use of inactive or out-dated antigen for the initial test, improper placement (subcutaneous rather than intradermal), and the booster effect of the initial test.[13–16] These factors do not explain the discrepancy between the results at CNM and SNM and the other five facilities, however. All of the initial testing was done at the same place, and the subsequent assignment to one of the seven facilities was not based on any factors which could conceivably influence converter rates. The possibility that over-reading of skin test reactions occurred at CNM and SNM seems unlikely. The education and preparation for this mass screening program was intensive and statewide. Most of the significant reactions were confirmed by a second observer, and most of the converters had induration of 15 to 25 mm, not borderline reactions.

Our failure to find any clustering of converters in individual housing units or any active index case or cases at CNM and SNM, while frustrating, was not too surprising. While prisons are close communities where contagious disease can spread easily, the turnover rate is high, and transfers from one facility to another within the system are frequent. The turnover rate among correctional staff is also high.

We concluded that the established tuberculosis screening policy had been inadequate. A few inmates had been missed in the intake testing program and more had been missed in the biennial retesting. Doubtful and insignificant reactions had not been retested at intake.

As a result of this experience, the tuberculosis surveillance program of the New Mexico Corrections Department has been revised as follows:

- Two-stage testing is done at intake on all inmates unless there is documentation of a past significant reaction. The first test is read at one week, and the second applied at that time to all with reactions of 0 to 9 mm.
- Inmates who give an undocumented history of a past positive test are retested at intake.
- Those with insignificant reactions in the two-stage initial testing are retested annually, with a single Mantoux test read at 48-72 hours. We chose annual testing because we want to monitor the current situation closely, and because we anticipate an increase in HIV infection. We want to be prepared to deal with the eventuality of reactivation tuberculosis in patients with HIV infection and to detect spread of tuberculosis in a timely fashion.
- Follow-up chest radiographs are done at one and two years on all those who refuse recommended INH, who are non-compliant with prophylactic treatment, or who have the drug discontinued for medical reasons. We are also intensifying our efforts to improve treatment compliance.
- A policy of screening all new correctional staff has been instituted, with two-stage skin testing.

TABLE 2—Results of Employee Screening

Facility	Employees	Screened		Negative	Reactors		Converters		Positivity Rate (%)*
		No.	(%)		No.	(%)	No.	(%)	
SNM	280	258	(92)	236	19	(7.4)	3	(1.1)	(8.5)
CNM	338	245	(72)	224	15	(6.1)	6	(2.5)	(8.6)

Immunization Coverage and Social Differentiation in Urban Senegal

DIDIER FASSIN AND EMILE JEANNEE

Abstract: We studied sociocultural factors associated with immunization coverage among a random sample of 500 mothers in the underprivileged suburbs of Dakar, Senegal. Factors associated with immunization of children under age 5 were maternal educational level and socioeconomic conditions (especially husband's regular salary); maternal age on arrival in town was more influential than total number of resident years in town; no effect of ethnicity was evident. (*Am J Public Health* 1989; 79:509–511.)

Introduction

Health behavior is strongly influenced by social variables, hence could also be used as an indicator of social differentiation. In developing countries, the recent growth of urbanization has created new social structures to which differences of origins, ethnicity, cultural background, economic level, age at migration, and duration of residence in town contribute in varying degrees. Classical studies in urban anthropology have shown how urbanization modifies traditional society and promotes different social practices,[1–3] but most studies of health behavior have taken little account of these changes,[4–6] as a recent review of literature on health interviews surveys showed;[7] nevertheless, comparative data taking socio-cultural variables into account are necessary for identification of risk factors and risk groups.

Immunization coverage is an objective indicator of health behavior in urban Senegal because differences in coverage cannot be related only to financial considerations (vaccines cost little) or to physical access (the WHO Expanded Program on Immunization covers the whole town).

The study to be described was carried out as a part of a multidisciplinary approach to urbanization and health in Africa. Field research was completed in Pikine, an underprivileged suburb of Dakar where slums of the capital were rehoused in the 1960s and 1970s. Population was estimated at 600,000 inhabitants in 1985 with a doubling period of five years over the past two decades. Primary health care is available through a Belgium-Senegalese project; a national program of immunization has been in effect for many years.

Methods

Study Population

Five hundred mothers were randomly selected through two-stage cluster sampling. Because no census list existed, we used a list of the 260 administrative districts, selecting 25 at random. In each district drawn, two blocks were randomly chosen on an updated map of Pikine. In the 50 blocks thus selected, interviews were held with the first 10 mothers who had at least one child under 5 years old, starting at the eastern corner of the block. If such a mother was not at home after two visits, another woman from the same block was included. When a man had several wives, each of them was seen separately. Interviews were conducted jointly by two investigators, one of whom was a woman who lived in Pikine. Interview schedules included questions on sociocultural items and access to health care; in particular, the mothers were asked whether the youngest child between one and five

years old had been immunized and the response was verified with the vaccination card in her possession.

Variables and Analysis

Sociocultural variables included ethnic group, age, marital status, maternal educational level, socioeconomic level, experience in town, and indicators of urban integration and village attachment. For *ethnic groups*, Wolofs and Lebus, Tukulors and Fulas, Bambaras and Soninkes, Diolas and Manjaks were respectively grouped together since the social structure and historical background of each member of the pair were closely related. For *socioeconomic level*, three different criteria were used: husband's regular salary, ownership of the house, possession of a couch; for *experience in town*, mother's age on first coming to town, the length of stay in town, the presence of child's father and or mother in town; for *urban integration*, use of Wolof as a communication language, participation in urban associations, knowledge of political local leader's name; for *village attachment*, use of mother tongue (for non-Wolof), participation in village associations, return to village in the past five years. Immunization coverage was considered absent if no vaccine had been given and present if partial or complete protection was noted against diphtheria, tetanus, whooping cough, poliomyelitis, measles, and yellow fever.

Results

Five hundred women were interviewed: eight were absent twice, 41 refused to answer, and thus 49 others were selected and interviewed. Sociocultural variables related to immunization coverage are: mother's educational level, husband's regular salary, ownership of their house, possession of a couch, mother's age on first coming to town, maternal parents living in town, mother-tongue speaking among non-Wolof, participation in village associations; recent return to village is negatively correlated to vaccination (Table 1). There are no important differences in immunization coverage among the largest ethnic groups (Table 2).

Discussion

Socioeconomic conditions and educational level are the main variables associated with immunization coverage. Although statistically correlated, the three criteria used for measuring the standard of living are not equivalent: having a salary means getting a regular income, as well as being protected by a social insurance for health problems; owning a house is less discriminatory, since middle-class households often prefer to rent an apartment in better districts, and poorer ones are very attached to any kind of property; finally, possessing a couch does not merely indicate objective "wealth" but also represents a status symbol.[8] The influence of socioeconomic conditions on immunization is not easy to understand at first analysis since vaccines only cost 100 FCFA, i.e., $0.3. Nevertheless, two strictly financial reasons can be proposed: although low in cost, this price may still prevent the poorest women from bringing their child to the dispensary for immunization; moreover, vaccines are sometimes unavailable through public outlets and people have to buy them in the private pharmacies where they cost 10 times as much. But poverty is also closely related to lack of education as is evident from this study; lack of education may prevent information about vaccination programs from reaching parents, as has been shown in Cameroon.[9]

Apparently the mother's early experience in town is a more important factor for her child's immunization than duration of her residence in town. The indicators of urban integration which we selected do not seem to have any influence on immunization coverage, perhaps because they were not discriminating enough; however, these same factors were associated with access to curative care for mothers and children in the same study.[10] They may be related to the ability to find one's way to a dispensary when ill, rather than attend a vaccination session whose existence is announced by loud-speakers. Our indicators of village attachment were supposed to measure the relationship of the women with their original rural community; but they apparently reflect different influences: recent return to village was negatively correlated to vaccination while the opposite was found for participation in a village association. The latter may indicate involvement in urban networks as well as traditional ties.[11]

Ethnicity is a central concept in social anthropology and traditionally considered as prominent in determinism of

behavior.[12] Nevertheless, in African cities, it has been shown that it is modified by other social factors: for example, unionism in the Cooperbelt area in South Africa is independent on the ethnic group of mine workers, but is correlated to the length of residence in an urban area;[13] an African townsman thus seems to be a townsman before being a member of his ethnic group.[14] In Senegal, Wolofs and Lebus represent the dominant group (43 per cent of total population) as well as the oldest one in the Dakar area. Tukulors and Fulas, on the other hand, have recently arrived in the capital from the Sahelian region. Serers are mainly peasants from the central part of Senegal. Other groups are minorities from Eastern (Soninkes, Bambaras) and Southern Senegal (Diolas, Manjaks). There is no difference in immunization coverage between Wolofs-Lebus and Tukulors-Fulas who have very similar socioeconomic levels, although their culture, history, and urbanization are quite different. And when all groups are considered in the same analysis, ethnicity does not appear to differentiate immunization coverage; the same findings were obtained for access to curative care.[10]

Determinants of health behavior in urban Africa are often described as "cultural." In the pluralistic medical system of cities, people would search for a therapy according to their ethnic and geographical origins. In the particular case of vaccinations which can be considered as an example of preventive health behavior, and in the specific context of the underpriviledged suburbs of Dakar, we have shown that educational level and socioeconomic conditions are correlated with immunization coverage, while ethnic distinctions are not a factor when determining risk groups in urban populations.

Prevalence of Diabetes in a Navajo Indian Community

JONATHAN SUGARMAN, MD, AND CAROL PERCY, RN

Abstract: The age- and sex-adjusted prevalence of non-insulin-dependent diabetes mellitus (NIDDM) of 494 (76 per cent) Navajo adults living in a reservation community was 10.2 per cent, approximately 60 per cent greater than the estimated prevalence (6.4 per cent) in the general U.S. population. The screening protocol utilized likely underestimates the prevalence of NIDDM in this population. A high proportion of Navajo people were overweight when compared to the general U.S. population. (*Am J Public Health* 1989; 78:511–513.)

Introduction

Diabetes mellitus is a public health problem of increasing importance for Native Americans. Diabetes in Southwest Indian tribes is almost exclusively non-insulin-dependent diabetes mellitus (NIDDM).[1] Most data regarding the prevalence of NIDDM in Navajo Indians, the largest Indian tribe in the United States, have been based on hospital chart reviews or on limited population surveys.[2] We therefore conducted a community-based screening program for NIDDM in adults in a representative sample of Navajo Indians.

Methods

The study was carried out from April 1, 1986 to March 31, 1987 in the Teec Nos Pos (TNP) Chapter, Shiprock Service Unit, on the 25,000 square mile Navajo Indian Reservation in northeastern Arizona. The 360 square mile area is inhabited almost exclusively by Navajo Indians.

Study Subjects

The 1986 population of the TNP Chapter was estimated to be 1,540.* By extrapolation from the Shiprock Service

Unit population, where an estimated 42 per cent of the population are 20 years of age or greater,** we estimated that 647 individuals in the TNP chapter were in this age group. The analyses were restricted to data for persons residing within the boundaries of the Chapter who were 20 to 74 years of age.

Approval to conduct the study was obtained from the local elected Health Board and the Navajo Area Indian Health Service institutional review board. Approximately 35 per cent of the subjects were screened at home and 13 per cent were screened at a local clinic. The remaining 52 per cent were screened in public places.

Screening was performed using capillary blood analyzed with a portable blood glucose monitoring system (Accu-Chek II Blood Glucose Monitors and Chemstrip bG Reagent Strips, Boehringer Mannheim, Indianapolis, IN). Fingersticks to obtain capillary blood were performed by nurses or other health care providers who were specially trained in the use of the instrument.

Individuals whose random blood glucose (RBG) levels were 7.8 mmol/l (140 mg/dl) or greater were referred to a clinical laboratory for fasting venous blood glucose (FBG) determination by a hexokinase method. Subjects whose FBG was greater than 7.8 mmol/l (140 mg/dl) were referred to Indian Health Service clinical providers for further evaluation and therapy.

The diagnosis of diabetes mellitus was made in persons with FBGs after an overnight fast of 7.8 mmol/l (140 mg/dl) or greater on two occasions, or with an RBG of 11.1 mmol/l (200 mg/dl) or greater plus classic signs and symptoms of diabetes mellitus.[3] Circumstances did not allow us to perform a formal glucose tolerance test. Blood glucose levels of subjects claiming to be diabetic at the time of screening were not always tested, although all diagnoses were subsequently confirmed by chart review according to the above criteria.

Weight and height were measured in subjects when possible. Weight-height index (W/H^p) was calculated in kg/m^p using $p = 2$ for males and $p = 1.5$ for females. Percentage of persons overweight at selected percentiles based on the weight-height index in the study population were compared to the United States rates.[4]

Age- and sex-adjusted prevalence rates were calculated using the 1980 US population as the reference population.[5] The US prevalence rates for diabetes were calculated for the above population using estimates of the numbers of diabetics aged 20–74 years.[6] Rates were age-adjusted to the 1980 US population by the direct method.

**Personal communication, Office of Program Planning, Navajo Area Indian Health Service

Results

Screening was performed on 76 per cent (494 individuals) of the estimated population age 20 years or older. Follow-up glucose testing was performed on 94 per cent (15/16) of those with RBG of 10.0 mmol/l (180 mg/dl) or greater, and 86 per cent (44/51) of those with RBG of 7.8 mmol/l (140 mg/dl) or greater who were not previously known to be diabetic. (A 72 year old male with a RBG of 21.2 mmol/l (382 mg/dl) who refused any follow-up testing or clinical interview was not counted as a diabetic in the prevalence calculations.)

The age and sex distributions of those screened were similar to those estimated for the TNP population, except that the screened group had a disproportionately low number of subjects under age 30 years, and males were slightly underrepresented in the study population. The age- and sex-specific prevalence rates of diabetes mellitus in the Teec Nos Pos chapter and the general US population are shown in Table 1. Twelve new cases (7 women, 5 men) of diabetes were diagnosed, and 36 previously known diabetics (23 women, 13 men) were identified. The crude prevalence rate of NIDDM in adults age 20–74 years was 9.9 per cent. The age- and sex-adjusted prevalence rate of diabetes in the TNP population ages 20–74 years was 10.2 per cent compared to the 1980 US rate of 6.4 per cent.

Data adequate to compute a weight-height index were available for 236 females and 164 males. A higher percentage of individuals in both sexes and all age groups (except males ages 20–24) were overweight in the study population than in the US population (Table 2).

Discussion

While the burden of infectious diseases in American Indian communities has decreased substantially over the past three decades, chronic illnesses such as NIDDM have become increasingly prevalent.[7] Diabetes mellitus was thought to be almost nonexistent among Navajo Indians before the 1940s, but subsequent surveys have shown large increases in the disease prevalence.[2]

No post-load glucose tolerance tests were performed in the present study. In addition, the screening procedure did not require an FBG. Thus, the prevalence rates of diabetes in the TNP Chapter are not directly comparable to those estimated from National Health and Nutrition Examination

*Weight-height in kg/m^p where p = 2 for males and p = 1.5 for females. Overweight criteria based on sex specific 85th and 95th percentile for persons age 20–29 years in NHANES I.[4]

Survey (NHANES II) data, which required that subjects meet the National Diabetes Data Group (NDDG) criteria after a 75 gram oral glucose load. Although our FBG 7.8 mmol/l (140 mg/dl) or greater is diagnostic of diabetes by NDDG diagnostic criteria, those criteria also allow the diagnosis of diabetes with a lower FBG plus elevated midtest and two-hour plasma glucose levels. Because only about one-fourth of the undiagnosed diabetics in the NHANES II study could be classified as diabetic solely on the basis of our FBG value, it is likely that the administration of a glucose tolerance test would have identified a higher prevalence of diabetes. In addition, because Type I (insulin-dependent) diabetes mellitus has rarely been described in full heritage southwestern American Indians,[1,8] the 1.6 ratio of the prevalence of NIDDM in the study population compared to that in the general US population, which includes persons with Type I diabetes, is underestimated.

The prevalence of NIDDM between the ages of 20 and 74 in the population of Navajo Indians studied exceeded that in the same age groups in the US population by approximately 60 per cent. The duration-specific prevalence rates of microvascular complications of NIDDM in Navajo Indians have been reported to be similar to those in other populations.[9] Thus, the high rates of NIDDM identified in the present study have significant clinical and economic implications for the health status and health care of Navajo Indians.

The large percentage of overweight individuals found in the population studied may contribute to the high prevalence of NIDDM. Because exercise programs for diabetes control have been successful in other Indian communities,[10] efforts at primary and secondary prevention by weight control and exercise are currently under way on the Navajo Reservation.

Uncompensated Emergency Care in Hospital Markets in Los Angeles County

GLENN A. MELNICK, PHD, JOYCE MANN, MSPH, AND ILANA GOLAN, MSPH

Abstract: A survey of hospital emergency rooms in Los Angeles County was conducted in March 1987. Analysis of the distribution of uninsured emergency care patients revealed that private hospitals play a significant frontline role in terms of entry into the hospital system for patients who are unable to pay—almost one-half of such patients were treated in the emergency rooms of private hospitals. Hospitals serving markets in which a higher proportion of residents had incomes below the poverty level provided a greater share of uncompensated emergency room services. (*Am J Public Health* 1989; 79:514–516.)

Introduction

As public and private third party payors impose market-oriented reforms in hospital payment methods, concerns have heightened over the effects of these policies on the uninsured population. Attention has been directed to the access problems of the medically indigent under these new payment approaches and to the problems of disproportionate share hospitals serving the medically indigent. The imposition of competitive pricing methods limits the ability of hospitals to subsidize the costs of uninsured patients. Growth of competitive-based insurance programs has been particularly strong in California, where they now cover over 60 per cent of the population.[1] Nationally, this number is approaching 25 per cent.[2] We discuss the distribution of unsponsored hospital emergency room care in a large metropolitan area in California and explore whether hospital market and financial characteristics influence provision of care to uninsured patients.

Methods

A survey of hospital emergency rooms in Los Angeles County was conducted by the Los Angeles County Medical Association and the Hospital Council of Southern California for a one-month period, beginning in March 1987. The survey collected data on the volume and costs of emergency room care provided to patients who were both uninsured and unable to pay (hereinafter referred to as uninsured). The costs of treatment included hospital and physician costs associated with emergency room services as well as hospital inpatient costs for uninsured patients who were admitted from the emergency room.

Both public and private hospitals were surveyed. Hospitals owned by Kaiser-Permanente, a closed system health maintenance organization (HMO), were excluded from the analyses since they serve members enrolled in Kaiser health plans and treat few, if any, uninsured patients. All four County-owned acute care hospitals and 51 of the 81 private hospitals with emergency rooms responded.

Hospital cost reports for fiscal year 1984 and discharge data for calendar year 1983 were provided by the California Office of Statewide Health Planning and Development. Emergency room charges for services rendered to uninsured patients as reported in the survey were reduced to costs using cost-to-charge ratios obtained from the hospital cost reports. We used patients' zip code of residence obtained from the discharge data to define each hospital's primary market area. The defined market area contained all zip codes that contributed at least 1 per cent of the hospital's discharges. If this rule did not result in a market area that contained at least 40 per cent of the hospital's discharges, additional zip codes were added (in descending order of patient volume) until a hospital's market area encompassed a minimum of 40 per cent of its discharges. We calculated the proportion of the population with income below the poverty level for each hospital's primary market area using 1980 census data.

Using multiple regression, we explored the role of several factors in explaining the wide variation among private hospitals in the volume and costs of care provided to uninsured patients. The independent variables included: ownership status, profit margin in a past year, hospital share of paying emergency room patients in the County, and the proportion of the population below the poverty level in a hospital's market area.

Results

Of all patients treated in the emergency room of responding hospitals, 19.8 per cent were classified as uninsured and unable to pay (see Table 1). A total of 36,304 such patients were treated in survey hospitals during the one month reporting period, incurring costs of $39.6 million. Although the four County hospitals provided treatment to the majority of uninsured patients, almost one-half of such patients were treated by the 51 private hospitals; the 15 private hospitals with trauma centers treated almost as many of these patients as the other 36 private hospitals.

Our estimates of the total number of uninsured emergency room patients and the total treatment costs incurred do not represent the total costs of treating such patients in the County since 35 per cent of hospitals with emergency rooms did not respond to the survey. Non-responding hospitals tended to be smaller than responding hospitals, having an average bed size of 198 compared to 312. All non-respondents consisted of private hospitals so the estimates of the relative burden of care borne by County-owned versus private facilities underestimate the contribution by private hospitals. However, we believe that this is not a significant problem since only one of the 16 trauma centers in the County were among the non-respondents. A telephone follow-up to a sample (eight hospitals) of the 30 non-respondents revealed that on average a low proportion of patients treated in the emergency rooms were uninsured and unable to pay.

On average two-thirds of the patients in County hospital emergency rooms are uninsured and unable to pay compared to 16 per cent in private hospital emergency rooms (see Table 2). Within individual County hospitals, the proportion of uninsured patients ranged from 48 per cent to 78 per cent, whereas within private hospitals, it ranged from less than 1 per cent to 42 per cent. Table 3 shows the distribution of uninsured patients among the hospitals.

Non-Trauma Center	36	8,691	23.9	48.9	3,899,340	9.8
All Hospitals	55	36,304	100.0	100.0	39,606,470	100.0

*This column refers to the proportion of all UUTP emergency room patients in the County that are treated by the hospitals in each group.

TABLE 2—Relative Burden of Uninsured and Unable to Pay Emergency Room Patients by Hospital Type, Los Angeles County, California, March 15–April 15, 1987

Hospital Type	Average Proportion of Uninsured Emergency Room Patients
	%
County	66.9
Private	16.1
Trauma Center	16.8
Non-Trauma Center	15.8
All Hospitals	19.8

Table 4 shows the estimated regression coefficients for each private hospital's share of the uninsured patients treated and for each hospital's share of the total cost of treating such patients.

The regression analyses show that hospitals with trauma centers provide a greater share of unsponsored care, both in terms of the number of uninsured patients and the total cost. Controlling for a hospital's share of paying patients, hospitals with trauma centers treat 1.6 per cent more of the uninsured patients and incur 2.1 per cent more of the costs of such patients on average than hospitals without trauma centers. Hospitals serving markets with higher poverty rates provide a greater share of services to this population. The estimated coefficient for a hospital's past profit margin is insignificant, suggesting that hospitals with higher profits in earlier periods do not use the surplus funds to provide a larger share of care to uninsured patients.

Discussion

Any solution to the problem of access to care for the medically indigent population needs to be broadly based and should address the complex issues surrounding access. Even though Los Angeles County has a large, publicly funded health care delivery system, private hospitals treat a substantial share (at least 45 per cent) of uninsured patients seeking emergency hospital care. Although the private hospitals transfer many of the patients to County-owned facilities, they play an important frontline role in providing entry into the health care system.*

County-owned hospitals treated 55 per cent of the uninsured emergency room patients but incurred 80 per cent of the total costs of treating such patients. The large share of costs borne by County facilities is likely due to several factors: 1) after providing initial treatment to uninsured patients, private hospitals often transfer these patients to County-owned facilities for further treatment; 2) County facilities may treat a more complex case mix of uninsured emergency room patients than do private hospitals; and/or 3) the average costs of County facilities are higher than in private hospitals.

Higher profit margins in a previous year do not lead to higher spending for care to uninsured patients, nor does a lower profit margin lead to lower spending. Unlike other parts of the United States, private not-for-profit hospitals in Los Angeles County provide only slightly more unsponsored care than do investor-owned hospitals.

*This may be particularly true in areas of Los Angeles County that are not near any of the County-owned facilities.

NOTES: The variable means are based only on the private hospitals in the sample since County-owned hospitals were excluded from the regression analysis.
Standard errors are in parentheses.

Changes in reimbursement policies in California (i.e., selective contracting by Medi-Cal and private insurers) are creating an increasingly competitive operating environment for hospitals. Hospitals located in areas with higher proportions of the indigent population will increasingly be at a competitive disadvantage. Recent attempts by hospitals in downtown Los Angeles to close their emergency rooms suggest that these pressures are already being felt.[3] Although the Medicare prospective payment system program provides extra payments to hospitals serving a disproportionate share of low income patients, this provision is scheduled to be discontinued in 1989. Emerging payment reforms need to recognize and incorporate provisions to ensure that access to medical care is not sacrificed in the effort to contain hospital costs.

ACKNOWLEDGMENTS

The authors would like to thank Kathleen Belkham of the Hospital Council of Southern California and Robert Holt of the Los Angeles County Medical Association for providing data for this study. We would also like to thank Professor William Shonick, Professor Paul Feldstein, and Carl Serrato for their helpful comments on drafts of this paper. This study was supported in part by a grant from the Robert Wood Johnson Foundation.

ADDENDUM

Background Information on Closure of Emergency Departments in Los Angeles as of September 1988

In May 1988, a private, not-for-profit hospital in downtown Los Angeles filed an application to "down-license" its emergency room from a full-service department to a standby facility that would no longer accept ambulances (it received approximately 800 ambulance visits per month). Soon afterward, three nearby hospitals filed similar applications, citing the potential increase in indigent patients if ambulances were re-routed to their facilities. Other hospitals have since threatened to follow suit.

As a short run solution, the County Department of Health Services provided $1.81 million in supplemental funding directly to eleven private hospitals that it believes are vital to the emergency services network. In return, the hospitals agreed to keep their emergency rooms open for the period of the contract. The County has agreed to provide an additional $1.25 million for a two-month period, but only on the condition that a statewide Tobacco Tax Initiative passes in the November election.

Of the eleven contracting hospitals, at least three had once been designated trauma centers but had withdrawn from the trauma network in 1987. Nine of the eleven are not-for-profit facilities, and the remaining two are investor-owned. Most are located in inner city areas. Absent a long run solution to the funding problem, the County could face a substantial reduction in the availability of hospital emergency department services.

Television Viewing and Obesity in Adult Males

LARRY A. TUCKER, PHD, AND GLENN M. FRIEDMAN, MD

Abstract: We estimated the extent to which time spent watching television is associated with obesity and super-obesity among 6,138 employed adult males. After adjustment for age, smoking status, length of work week, measured physical fitness, and reported weekly hours of exercise, people who viewed TV more than three hours/day were twice as likely to be obese as those who viewed less than 1 hour/day. Those who viewed for 1 to 2 hours daily had a relative risk of 1.60 (1.21, 2.11). Physical fitness consistently confounded the associations between TV viewing and obesity/super-obesity, but the other control variables did not do so. (*Am J Public Health* 1989; 79:516–518.)

Introduction

Television viewing is the most pervasive pastime in the United States today. Following sleep and work, it is the nation's third most time-consuming activity.[1] The typical adult watches TV nearly four hours daily[1,2]; hence, it is not surprising that contemporary research indicates that human beliefs and practices are affected by television to a degree far exceeding earlier judgments.[1,3]

The role television plays in the development of health-related attitudes and behaviors is of growing interest to many.[4] Studies of the content of this powerful medium suggest that many health messages are conveyed regularly to viewers. Unfortunately, the information is sometimes unrealistic, distorted, and misleading,[7] particularly regarding food, nutrition, and obesity.[8–14]

Although many of the "micro-lessons" to which Americans are regularly exposed may promote misconceptions and produce unhealthy eating habits, television's primary offense may be one of omission rather than commission.[15] Research has shown repeatedly that the medium has profoundly altered American leisure.[1,16] When the TV is on, activity ceases and time for exercise is reduced significantly. The heart and other muscles of the body are not strengthened and calories are not expended in excess of resting metabolism during television viewing.

Recently, Tucker[17] examined the relation between television viewing and physical fitness. Results showed that as TV watching increased among 379 high school males, multiple measures of physical fitness decreased markedly and systematically. Similarly, Dietz and Gortmaker[18] showed that as TV viewing increased among several thousand children, obesity increased substantially.

The present study measured the extent of the association between TV viewing and obesity among adult males; an ancillary objective was to determine the extent to which age, cigarette smoking, physical fitness, time reported exercising, and hours worked per week mediate the relation between the television viewing and obesity.

Methods

Study subjects were 6,138 adult male employees of over 50 different companies that participated in the Health Examination Program offered by Health Advancement Services (HAS), Inc. Approximately 77 per cent of the subjects were married, 85 per cent were white, 51 per cent had some college education, and 32 per cent of the subjects were current smokers. The mean age

was 39.5 (SD = 10.2) and the median and modal gross family income was $25,000–$30,000. Approximately 50 per cent of the subjects classified their jobs as professional or technical and 27 per cent as managerial/administrative.

All data were collected by registered nurses employed by HAS. Each subject was examined individually and privately for approximately 50 minutes after participating in a general orientation and completing an informed consent form. A written questionnaire was administered to assess demographic information, time spent watching television per day, number of cigarettes smoked per day, hours worked per week, and time spent exercising per week. Using a Harpenden skinfold caliper, subcutaneous fat was assessed at: *thigh* (anterior aspect midway between the hip and the knee-vertical fold), *chest* (half the distance between the anterior axillary line and the nipple-diagonal fold), *abdomen* (laterally at a distance of 2 centimeters from the umbilicus-vertical fold). The sum of the skinfold measurements along with age and gender were used to calculate the total body fat percentage of each subject. Physical fitness was assessed using a step test, the 3-minute Pulse Recovery Test.[19]

Obesity was treated categorically since body fat percentage poses little concern or risk until elevated levels signifying excessive fat are attained. Specifically, obesity was defined as 21 per cent to 30 per cent body fat[20]; males with 31 per cent or more body fat were considered super-obese. Television viewing and the control variables were categorized as shown in Table 1.

The relation of obesity and super-obesity to television viewing was measured by the odds ratio[21] with infrequent television viewers as the reference group. Mantel-Haenszel summary risk estimates were used to control for potential confounders. The relation of the control variables to television viewing and obesity was measured by the Mantel-Haenszel chi-square statistic.[22–24]

Results

As shown in Table 1, most subjects reported one to two hours of television viewing per day: more television viewing was reported by younger subjects, by the less fit, by smokers, by non-exercisers, and by subjects working fewer hours. Obesity or super-obesity, measured in nearly one-third of the subjects, varied markedly according to age, measured fitness, and reported exercise but not with smoking status or length of work week.

Table 2 shows the estimated relative risk of obesity by television viewing time without adjustment, with adjustment for all of the control variables identified in Table 1, and with adjustment only for measured fitness, the only actual confounder. After adjustment, subjects who viewed three hours of television or more each day showed twice the risk of obesity and even greater risk of super-obesity.

Discussion

The present findings indicate that duration of daily television viewing is strongly associated with obesity and super-obesity in adult males, as in children.[18] The associations could mean that: obesity causes increased television viewing; that obesity and television viewing are each caused by other common factors; or that increased television watching causes obesity.

By the first interpretation, men who are fat may be attracted to watching television as a primary source of recreation or entertainment, whereas non-obese men may prefer other pastimes, since most leisure activities require more physical exertion than television watching.

If the second interpretation is correct, the data suggest that the common correlate confounding the association is not age or length of work week. Smoking may confound among adolescents,[25] but it did not confound in this adult population.

The confounding effects of time reported exercising and physical fitness on the TV viewing/obesity relationship have not been studied previously; in these data, both were inversely related to television viewing and to obesity. Adjustment for time reported exercising (a subjective measure) reduced the relative risk estimates by only 4 per cent on the average, while adjustment for measured physical fitness reduced the estimates by 13 per cent for obesity and 28 per cent for super-

*Unable to calculate because of insufficient subjects in the frequent viewers super-obese subgroup and the many strata of the control variables.

obesity. Nonetheless, television time and obesity were strongly related even after holding fitness constant.

If the third interpretation is correct, a possible mediator, unmeasured in the present study but equal in theoretical importance to time spent exercising and physical fitness, is caloric intake. Because television viewers are bombarded by thousands of messages for nonnutritious foods via advertisements and prime-time programs,[9,10,14] and because television viewing correlates with snacking and consumption of foods advertised on television,[7,26,27] it is possible frequent viewers consume significantly more calories than their counterparts, and hence are more obese.

Future research on the association of television viewing and obesity will need to consider this factor. In addition, because subjects in this study had relatively high SES (socioeconomic status), generalization to poorer groups will require additional research.

With the growth of cable television, home video recording, and videogames, television viewing is likely to increase in the coming years. The findings of this study and other recent research show that the impact of television on the lifestyles and health of Americans cannot be ignored.

Trends in Dental Fluorosis and Dental Caries Prevalences in Newburgh and Kingston, NY

JAYANTH V. KUMAR, DDS, MPH, ELMER L. GREEN, DDS, MPH, WILLIAM WALLACE, MS, AND TAIMI CARNAHAN, PhD

Abstract: A study was undertaken in New York State to determine the changes in dental fluorosis prevalence from 1955 to 1986 in fluoridated Newburgh and non-fluoridated Kingston children. The frequency and severity of dental fluorosis among 884 7–14-year-old children were measured by two dentists utilizing Dean's Index. Data regarding residential and fluoride history were obtained from the parents of participants. Among the Newburgh residents, the prevalence of dental fluorosis (very mild to moderate) varied from a low of 5 per cent for the 9–10-year-old group to a high of 9.4 per cent for 11–12-year-olds. Except for the 13–14-year-old group, children in non-fluoridated Kingston had the lowest dental fluorosis prevalence rates. A comparison of Dean's Community Fluorosis Indices to the 1955 baseline data obtained from studies conducted after 10 years of fluoridation in Newburgh revealed no changes of consequence among Newburgh residents. However, the changes are apparent for Kingston residents, indicating the availability of fluorides in non-fluoridated areas. The increased risk for dental fluorosis for Kingston residents appears to be from the use of fluoride tablets. An analysis of dental caries data revealed that caries prevalence declined substantially in both fluoridated and non-fluoridated areas. (*Am J Public Health* 1989; 79:565–569.)

Introduction

Oral health surveys conducted in the United States and other developed countries have demonstrated that the prevalence of dental caries in children has declined substantially in recent years.[1–8] The increased availability of fluoride in many forms appears to be the single most important factor. The use of antibiotics, improved levels of restorative care, and patterns of sugar consumption and snacking have also been thought to contribute to the secular changes.[1,9–11]

To explain changes in dental caries prevalence in non-fluoridated areas, many investigators have pointed out the effect of systemic fluorides in professionally prescribed supplements and/or the use of fluoridated dentifrices by young children.[1,12–15] The increased availability of fluorides in food has also been suggested.[13,16–21] Singer and his co-workers have indicated that the average daily fluoride intake for infants, two-year-olds, and young male adults is within the accepted range of 0.05 to 0.07 milligram per kilogram body weight and has not significantly changed over the past 30 years.[22–25] However, studies of fluoride levels of baby formulas and cereals have shown a significant increase in the fluoride content when fluoridated water was used for processing these foods.[12,19,27–29]

Additional sources of fluorides are available now that were almost nonexistent when water fluoridation standards were determined. These include fluoride rinses and fluoride dentifrices. Barnhart, *et al.*[30] reported that 2- to 4-year-old children ingested an average of 0.3 gram (gm) of dentifrice or 0.3 milligram (mg) of fluoride per brushing. Fluoride supplements are commonly prescribed for children living in non-fluoridated areas.

The availability of fluoride from multiple sources has raised questions about the potential for increases in the incidence of dental fluorosis. Aasenden and Peebles[31] found that 67 per cent of the children who ingested 0.5 mg fluoride from birth to three years of age and 1.0 mg daily thereafter had very mild to mild enamel fluorosis and 14 per cent had moderate fluorosis. In a later report, they suggested that fluorosis might become less noticeable with age.[32] Hennon and co-workers[33] reported no unacceptable levels of fluorosis among children who resided in communities with 0.6 to 0.8 ppm fluoride in the water and had taken 0.5 mg fluoride supplements from birth to age 3 years. Recently, Soparkar, *et al.*,[34] reported an unexpectedly high proportion of children with enamel fluorosis and the source of fluoride was determined to be prescribed fluoride supplements. Oldak and Leverett[35] observed an increased occurrence of dental fluorosis in children residing in non-fluoridated communities. Twenty-two per cent of children ages 6–8 residing in a non-fluoridated community had fluorosis in permanent teeth. This higher than expected level of dental fluorosis was thought to be due to the prior use of dietary fluoride supplements.

Recently, Driscoll, *et al.*,[36,37] and Segreto, *et al.*,[38] compared data on the prevalence of fluorosis with historic data and found no important changes in the prevalence and severity of fluorosis. Although mean fluorosis indices were within the normal range in Rochester, New York, a higher than expected prevalence of very mild categories of fluorosis was reported by Leverett.[39]

Most epidemiological studies of dental fluorosis have been conducted in the Midwestern States, but baseline data on the frequency and severity of dental fluorosis in New York State are available from the 1955 Newburgh-Kingston Study.[40] Therefore, an opportunity existed to determine if the frequency and severity of dental fluorosis had changed over the last 30 years in those two cities.

Similarly, changes in dental caries prevalence could also be determined. Studies conducted between 1944 and 1955 in Newburgh indicated that dental caries prevalence declined considerably after fluoridation. In the non-fluoridated Kingston, dental caries prevalence increased during the same period. Another study of 13- and 14-year-old children in Newburgh and Kingston revealed that this trend continued into the early 1960s.[40–42]

Methods

Between 1955 and 1986, several demographic and socioeconomic changes have occurred in both Newburgh and Kingston. Compared to Kingston, Newburgh has: a lower median income, a slightly larger proportion of low income level households, a lower median school years completed, a lower percentage of White population, a slightly higher percentage of unemployed, and a different occupational distribution.[43] The water supply records in Newburgh indicate that the level of fluoride in the water was maintained at the recommended 1 ppm established by the US Public Health Service in 1945, except for a three-year period from 1978 to 1981. This reduction in fluoride would affect the teeth of 7- to 14-year-olds differentially, depending on the stages of development of the teeth during this time. The city of Kingston has a fluoride content of 0.3 ppm in water.[44]

To obtain estimates of prevalences of dental fluorosis and dental caries in the cities of Newburgh and Kingston, children attending grades one through eight in public schools were selected to participate on the basis of a stratified random sampling of clusters. A total of 1,446 children from five elementary and two junior high schools in Newburgh and 694 children from four elementary and two junior high schools in Kingston agreed to participate in clinical examinations. The response rates were 63 per cent for Newburgh and 50 per cent for Kingston. The overall response rates were 72 per cent and 38 per cent for elementary and junior high schools, respectively.

Dental fluorosis was determined for each child according to the established classification by Dean, in which the child is classified on the basis of the two teeth in the mouth showing the most advanced signs of fluorosis.[45] In order to differentiate fluorosis from other enamel defects, the criteria developed by Russell was used.[46] Dental caries was assessed using World Health Organization (WHO) guidelines.[47] A pretested questionnaire was used to obtain residential and fluoride history from the parents of participants.

Two dentists, who were not involved in New York State fluoridation or fluoride supplement programs, independently examined approximately equal proportions of participants in Newburgh and Kingston. Examination equipment included a portable chair and a fiber optic light source. The examiners were trained by an outside consultant in applying Dean's classification and were standardized four times during the study. Further, as an attempt to incorporate blindness, children who were not continuous residents of Newburgh and Kingston were also examined. The residential and fluoride history data were not made available to the examiners.

The analysis of data is limited to groups of children between ages 7 and 14. Children under age six and over age 15 were excluded because of inadequacies in the sample size. Children with orthodontic bands or only deciduous teeth were also excluded. Estimates of community fluorosis indices and respective standard errors were calculated for comparison purposes using the methods appropriate for stratified cluster sampling.[48] Trends in dental caries prevalences were determined by comparing age-race adjusted decayed, missing, filled, teeth (DMFT) indices. The relationship between fluorosis and dental caries was determined by analysis covariance technique. The adjusted mean scores were derived by treating age as a covariate utilizing the SAS-GLM computer package.[49]

Because a large number of children attending the schools in Newburgh City were from the non-fluoridated town of New Windsor and the recently fluoridated town of Newburgh, the children were separated into distinct groups. As the amount of exposure to fluorides is of particular importance, data analysis is limited to continuous residents of Newburgh and Kingston. For the purpose of this report, 993 children who were not lifetime residents of Newburgh or Kingston cities were excluded from the analysis. Because the prevalence and severity of fluorosis did not differ significantly by ethnic group, sex, or examiners, only summary data are presented. As age-specific fluorosis rates tended to be unstable, data are presented by two-year age intervals.

Results

The characteristics of the study population by relevant variables are presented in Table 1. There are smaller proportions of White and a generally lower set of socioeconomic indicators in the Newburgh sample and somewhat fewer lifetime residents (14 per cent vs 16 per cent).

The frequency and severity of dental fluorosis for the children examined is presented for the two community groups in Table 2. Among the residents of the fluoridated Newburgh City, as well as residents of Kingston, the majority of the detectable dental fluorosis lesions observed were in the very mild category.

Among the Newburgh residents, the prevalence of dental fluorosis (very mild to moderate categories) varied from a low of 5 per cent for the 9–10-year-old group to a high of 9.4 per cent for 11–12-year-olds. Except for the 13–14-year-old group, children in the non-fluoridated Kingston had the lowest dental fluorosis prevalence rates. The relation between age and dental fluorosis prevalence was inconsistent.

When the distribution of the lesions on the worst affected tooth of each child was analyzed, the clinical manifestation of the lesions observed in Newburgh and Kingston was similar (Table 3).

A comparison of Dean's community fluorosis indices among the populations reveal that there are no differences in 1986 between Newburgh and Kingston residents (Table 4). Table 4 also compares the Dean's community fluorosis indices to the baseline data obtained from 1955 studies conducted after 10 years of fluoridation in Newburgh and Kingston. Although changes in the prevalence of dental

13–14	0.00*	0.20 (.05)	0.00	0.19 (.05)

*Newburgh children of this age group did not receive fluoridated water during the formation of teeth.

NOTE: The 1955 Community Fluorosis Indices for Newburgh and Kingston residents were calculated from the frequency and severity of Dental Fluorosis.[40]

fluorosis are not apparent among Newburgh residents, changes for Kingston residents were detected.

A history of the use of fluoride tablets/drops during the first eight years of life from the parental questionnaire may indicate the exposure to a known risk factor. Table 5 shows that approximately 31 per cent of the children in Kingston reported a history of regular use of fluoride tablets/drops compared to 5 per cent for the residents of Newburgh. The odds ratio calculated for the two groups indicated a greater odds of developing dental fluorosis when tablets were taken every day. Over 95 per cent of the children in both groups reportedly use fluoride dentifrices. The effect of other sources of fluoride, such as topical rinses and professional fluoride applications was not examined.

A comparison of the data gathered from studies conducted in Newburgh and Kingston reveals that caries has declined both in fluoridated and non-fluoridated areas (Figure 1). Figure 2 demonstrates the caries trends in 13- and

TABLE 5—History of Fluoride Tablets/Drops Use and the Estimated Relative Risk with Everyday Use of Tablets/Drops during the First Eight Years of Life

	N	Fluoride Tablet/Drops History			Odds Ratio*
		About Every Day	About 3 Days/Week	Occasionally	
Newburgh	459	24 (5%)	1 (0%)	47 (10%)	1.7
Kingston	425	133 (31%)	16 (4%)	46 (11%)	3.8

*Indicates the ratio of the prevalence of dental fluorosis among those who reported everyday tablet/drops use compared to those who did not report tablets/drops use.

Odds Ratio (Newburgh) = 3/24 ÷ 28/387 = 1.7 (95% CI = −0.5, +3.9)

Odds Ratio (Kingston) = 20/133 ÷ 9/230 = 3.8 (95% CI = +.07, +6.9)

14-year-old children.

A comparison of dental fluorosis and dental caries prevalence suggests an inverse relationship. Children with very mild to moderate dental fluorosis consistently had lower caries experience (Table 6). The covariate adjusted mean DMFS indices showed that children with very mild to moderate fluorosis had approximately 41 to 54 per cent fewer DMFS, respectively.

Discussion

Although demographic and socioeconomic changes over a period of four decades have resulted in population differences between Newburgh and Kingston, an analysis of trends in fluorosis prevalence should be still valid. Segreto, *et al*, have reported that the effect of gender, ethnic group, or family income in dental fluorosis is small compared with the effect of optimal fluoride level in drinking water.[38] The changes in dental caries prevalence in Kingston must be viewed in light of the effect of changes in socioeconomic characteristics and the impact of the availability of other forms of fluoride in non-fluoridated areas.

The results indicate that the extent and severity of dental fluorosis among residents in an optimally fluoridated community in a Northeastern State is within the normal range, as specified by Dean. Dean has stated that the mildest forms of dental fluorosis would occur in about 10 per cent of a population that used water containing about 1 ppm of fluoride continuously from birth.[50] Later, he suggested a method to

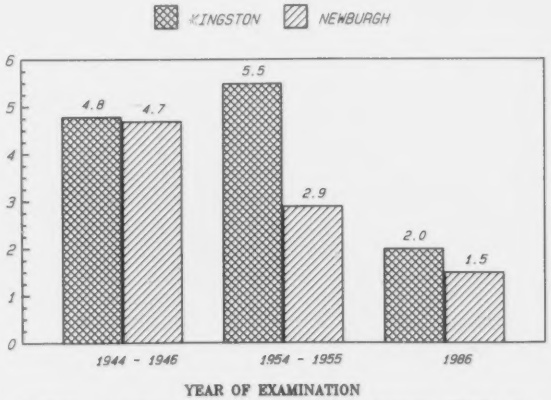

FIGURE 1—Age-Race-Adjusted Dental Caries Prevalence (DMFT) for 7–14-Year-Old Children in Newburgh and Kingston, NY, 1944–86

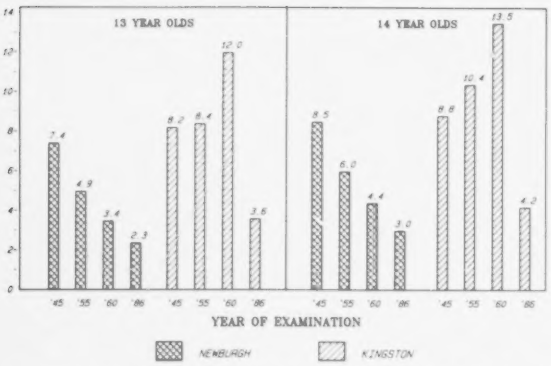

FIGURE 2—Dental Caries Prevalence for 13- and 14-Year-Olds in Newburgh and Kingston, NY, 1944–86

ascertain the public health significance of dental fluorosis utilizing the Community Fluorosis Index (CFI). According to Dean, CFI scores below 0.4 are considered as having no public health significance.[51] Because 99 per cent of the population studied had less than moderate categories of dental fluorosis and the differences over time were negligible, these data suggest that no changes have occurred in the past three decades. This observation is consistent with the recent studies conducted by Segreto, *et al*, in Texas,[39] and by Driscoll, *et al*,[36,37] in Illinois.

The lower community fluorosis indices for all age groups for Newburgh residents compared to those reported elsewhere[36–39] for residents of other fluoridated communities could be due to three years of interruption in fluoride availability from water. However, an analysis of the relation between age and fluorosis prevalence did not reveal any consistent effect of this interruption. The 13–14-year-old group that received an uninterrupted supply of fluoride from birth for seven years did not have any more fluorosis than the 7–8-year-old group that received the least amount of fluoride exposure from water. Also, the fact that 16 per cent of Newburgh resident children also reportedly received fluoride tablets may indicate that some of these children received fluoride during the period of interruption in water fluoridation. Further, compared to other indices that consider the tooth as a unit, the use of Dean's Community Fluorosis Index based on the child as a unit minimizes the underestimation resulting from interruption in fluoride availability, because any excessive exposure during the development of teeth will affect at least some teeth. This manifestation is considered as fluorosis, no matter whether the child received fluoridation during the development of some teeth or all the teeth.

Another possible explanation for the low community fluorosis indices may be due to differences in the application of the diagnostic criteria. This may have been minimized by not providing the fluoride history to examiners and by the high level of agreement among the examiners. A comparison to an earlier study in Newburgh and Kingston conducted by Russell in 1955 should take into consideration the differences that could have occurred in the application of the diagnostic criteria. The community fluorosis indices reported in 1955 for Newburgh residents were also lower compared to that of other studies.[45] However, at that time, only 7–8-year-old children had received fluoride in drinking water continuously from birth.

TABLE 6—Dental Caries Prevalence According to Dean's Fluorosis Classification

Dean's Fluorosis Classification	N	Covariate (Age) Adjusted Mean DMFS	Standard Error
Normal	704	2.2	0.11
Questionable	113	2.1	0.27
Very Mild	41	1.3	0.47
Mild	19	1.1	0.67
Moderate	7	1.0	1.11

The change in the occurrence of very mild to mild categories of dental fluorosis from the original study is noticeable in the non-fluoridated city of Kingston. This increased occurrence of fluorosis in non-fluoridated areas has been reported by other investigators.[4,34,35]

In Kingston, the increased occurrence of fluorosis may be attributed to a large extent to the use of fluoride supplements. If the use of infant formula was similar in the studied populations and the cases and controls are representative of the population, then an important factor associated with dental fluorosis is the use of fluoride tablets/drops. The fact that this group received fluoride supplements at a higher than the currently recommended dosage may have contributed to an increased risk for developing fluorosis.[52]

The higher dental fluorosis rate reported for Kingston when compared to the studies conducted in other non-fluoridated areas is consistent with the variation in the fluoride supplement use in different regions of the country.[34–39] The findings from the 1983 National Health Interview Survey indicated that the use of fluoride supplement was more frequent among White families with high incomes in the Northeastern regions.[53]

Dental caries declined substantially both in Kingston and Newburgh, a trend that is consistent with the recent findings from other studies.[1–9,13] An observation of particular interest is that between the 1940s and 1960s, dental caries increased in the non-fluoridated Kingston in contrast with the fluoridated Newburgh. As a result of this phenomenon, the caries decline between the 1960s and the 1980s in Kingston appears to be greater in Kingston compared to Newburgh. In spite of this decline in caries in the non-fluoridated area, lower caries prevalence continues to exist in the fluoridated area. However, factors such as differences in the service utilization patterns as evidenced by the comparison of the proportion of filled component of all caries surfaces, interruption in the fluoride availability for Newburgh children, and an increased availability of fluorides for Kingston children complicate the measurement of impact of fluoridation in this study.

An analysis of dental caries prevalence, according to Dean's fluorosis classification, revealed that children with very mild to moderate to dental fluorosis had 41 to 54 per cent lower caries prevalence. Driscoll, *et al*, observed similar differences among children residing in areas where the fluoride is above optimal levels.[37] The additional caries inhibitory effect for children with very mild to moderate dental fluorosis observed in the original studies appears to still exist.[51] Several researchers have suggested that the logical implication of an inverse relationship between dental caries and dental fluorosis in the development of public policy is that a slightly increased risk for dental fluorosis is preferable to a higher risk for dental caries,[57,58] since the very mild to mild categories of fluorosis are neither an adverse health effect nor esthetically objectionable, whereas dental caries results in pain, suffering, loss of esthetics, and higher costs.

ACKNOWLEDGMENTS

This study was supported by a grant from the Dental Disease Prevention Activity, Centers for Disease Control, Atlanta. The authors would like to thank:

- Dr. Dennis Leverett for providing assistance in calibration and standardization;
- Drs. Margaret Scarlett, Susan Szpunar, and Ronald Hunt for helpful suggestions on earlier drafts;

Survey of Cause-of-Death Query Criteria Used by State Vital Statistics Programs in the US and the Efficacy of the Criteria Used by the Oregon Vital Statistics Program

DAVID D. HOPKINS, MS, JOYCE A. GRANT-WORLEY, MS, AND TERRIE L. BOLLINGER

Abstract: A survey of the 52 vital statistics registration areas in the United States revealed that at least 23 did not fulfill the minimum cause-of-death query guidelines recommended by the National Center for Health Statistics. The Oregon Center for Health Statistics is one of only a few that query certifying physicians at a comprehensive level. During August 1986–July 1987, a total of 2,453 of 23,238 death certificates were returned to the certifiers for additional information, not including those returned in a tobacco use study. More than one-half (56.1 per cent) resulted in new and more specific underlying cause-of-death data. Only 5.2 per cent of the queries were unanswered.

One probable result of Oregon's program is that the state has the highest percentage of liver cirrhosis and disease deaths attributed to alcohol abuse in the United States. Nationally, 41.7 per cent of all liver disease and cirrhosis deaths in 1984 were listed as due to alcohol compared to 82.4 per cent in Oregon. The state's total liver cirrhosis and disease death rate (12.0 per 100,000 population) is only marginally higher than the United States rate (11.6). The query program also serves to locate maternal deaths that would otherwise not be reported, as well as to provide more accurate cause-of-death statistics in general. (*Am J Public Health* 1989; 79:570–574.)

Introduction

Health statistics play an important role in revealing the existence and extent of health problems, both locally and nationally. Perhaps the most fundamental measure of the health status of any population is the life-death dichotomy. Mortality statistics are widely available in the United States for various populations but, since the vital statistics system is state-based, are the data collected in a comparable manner?

The underlying cause of death (the disease or injury that started the sequence of events leading directly to death) is a difficult concept for some physicians. These physicians often report the cause of death solely as a mode of death such as cardiac arrest or respiratory failure. The querying of certifying physicians by state vital statistics offices has long been recognized as an important method of improving the accuracy of statistics generated from death certificates; it also serves to educate physicians on how to properly record the cause of death.

In the United States, death certificates are collected by the 50 states plus two other vital statistics registration areas* (New York City and the District of Columbia). The information on cause of death reported by the certifying physician is coded by either the state nosologists, or by nosologists at the National Center for Health Statistics (NCHS) from copies of the death certificates. The NCHS is entirely dependent on the states to query physicians regarding certificates that were not completed satisfactorily. In June 1985, the NCHS published recommended criteria for cause-of-death querying.[1]

NCHS has described six priority levels for querying, with Level 1 consisting of the minimal amount of querying necessary "to promote the basic integrity of state and national data," and Level 6 being the most comprehensive level.[1] The six levels were developed recognizing that the availability of staff and resources vary from state to state but that Level 1 items should always be queried. Level 1 causes to be queried include entries such as "heart disease," "adult respiratory distress syndrome," and "senility." Each higher priority level provides additional detail. For example, the specific site of a malignant neoplasm of the pancreas is queried at Level 5.

This report summarizes the results of the survey of cause-of-death querying practices in state vital statistics programs. It also describes the procedures used by the Oregon Center for Health Statistics (OCHS) to assure that mortality statistics are as accurate as possible and the effect of the procedures on cause-of-death rates.

Methods

Oregon has had a cause-of-death query program for many years. Prior to 1983, nosologists manually selected certificates requiring further information. Beginning in 1983, query criteria were formalized, with a list of most certificates requiring queries generated by computer. Three months after the NCHS published recommended criteria for cause-of-death querying in June 1985,[1] the OCHS implemented a revised automated query generation system based upon NCHS guidelines. A small number cannot be selected automatically and require individual selection by nosologists. A separate list is generated, for example, when causes suggestive of AIDS (acquired immunodeficiency syndrome) (Appendix A) are listed but AIDS itself is not mentioned on the death certificate.

The OCHS chose to select certificates for query at priority Level 4, the most thorough level recommended for general querying. Levels 5 and 6 are "frequently required for specified special studies."[1] Additionally, the OCHS queries physicians on a few Level 5 criteria and for some causes not listed by the NCHS (see list in Appendix B). The OCHS no longer queries for some format problems, congestive heart failure, or mental conditions as recommended by the NCHS because, in our experience, these queries drew only useless or irate responses from physicians.

The OCHS uses 27 basic formats for query letters. Each letter measures 21.6 × 12.7 cm and is photocopied adjacent to the death certificate in question, resulting in a legal-sized single sheet of paper containing a copy of the certificate and query form. This is then customized, if necessary, and mailed to the certifier along with a flyer explaining the query program and highlighting common problems requiring queries. The letters used by the OCHS are more specific to the cause in question than the sample letters developed by the NCHS.

Each query is subsequently categorized in one of five groups: 1) No response, 2) Responded with inadequate information, 3) Responded with adequate information but no changes, 4) Responded with adequate information resulting in a change to the underlying cause-of-death, 5) Responded with adequate information not resulting in a change to the underlying cause but resulting in additional cause-of-death information (such as substance abuse which is tracked with supplemental codes).

To compare Oregon's query procedures with those of other states, a questionnaire was mailed to each state registrar on October 20, 1986. Three questions were asked: 1) Do you use Part 20 of the NCHS Instruction Manual? 2) If so, what priority level do you use? 3) If not, what other criteria do you use? After a follow-up letter, all state registrars except those from Maryland, Massachusetts, Virginia, and New York City had returned their questionnaires.

Results

The Oregon Program

We report the outcome of 2,453 cause-of-death queries made on 23,829 certificates during August 1986–July 1987. These do not include tobacco use queries which are discussed later.

The response rate by physicians to queries is very good, 94.8 per cent. This includes 0.4 per cent who responded, but with inadequate information, and 34.8 per cent who responded with adequate information that did not result in a change to the underlying cause-of-death code. However, some of the queries in this category yielded new supplemental codes and additional external cause-of-death information. Beginning in January 1987, a new code was created to track queries that resulted in changes to the certificate but that did not affect the underlying cause-of-death. Six per cent of the 1987 certificates were so categorized (3.5 per cent during the entire study period). More than one-half of the queried items (56.1 per cent) resulted in more specific underlying cause-of-death data. This includes 1.0 per cent of the queried certificates that were recoded as a result of the nosologist reading selected medical examiner files.

Response by Type of Query Form

The most commonly used form accounts for 40.4 per cent of the total. It asks for the underlying cause of the stated condition; 49.0 per cent of these queries generate responses that result in a change of the underlying cause-of-death. The three most frequently queried causes are: *cardiac arrest* (with 55.7 per cent ultimately reassigned to the underlying cause), *septicemia* (49.4 per cent), and *renal failure* (54.4 per cent). Only two other forms are used more than 5.0 per cent of the time; one asks if the *primary site of a carcinoma* with an unspecified site was known, while the other is a letter customized for individual certificates with *conflicting or missing information*. Both result in more specific and/or accurate causes of death in about 55 per cent of the cases.

Eight of the forms result in new cause-of-death codes at least 80.0 per cent of the time. Queries regarding motor vehicle and watercraft accidents generated the largest percentage of new underlying cause-of-death codes. The form that generates the lowest percentage of changes in the underlying cause-of-death asks, "Was this woman pregnant within 42 days prior to her death?" Nonetheless, this is how the OCHS locates many maternal deaths, because not all physicians note the fact on death certificates. Female deaths meeting the criteria listed in Appendix B are queried.

In May 1987, the OCHS began querying certifying physicians to ascertain if tobacco use contributed to the death of the decedent when one of the following conditions was listed as the cause-of-death: lung cancer, bronchitis, emphysema, and chronic obstructive pulmonary diseases (COPD). Tobacco use was chosen for query because the death rates for these causes were 10.9, 33.3, 55.9, and 22.2 per cent higher, respectively, for Oregon than for the nation during 1985; Oregon has had elevated death rates for these causes for several decades.

Six hundred ninety-one deaths from these causes were recorded from May to August and 427 queried because the physicians failed to note the role of tobacco, if any. Only 3.7 per cent of the physicians failed to respond. Tobacco use was reported to have contributed to, or caused, the following deaths: lung cancer, 76.9 per cent; bronchitis, 70.0 per cent; emphysema, 81.8 per cent; COPD, 76.6 per cent. The OCHS records this information with a supplemental code because International Classification of Diseases (ICD)[2] and NCHS rules[3,4] do not permit the underlying cause-of-death to be coded to tobacco use when the tobacco has been reported as the cause of the above conditions. Prior to querying, tobacco use was mentioned on only 8.5 per cent of the certificates when the underlying cause was one of the four causes listed above. A question regarding tobacco use was added to the Oregon death certificate in January 1989 as a consequence of the data generated by the query program. It applies to all deaths, not just lung cancer and chronic obstructive pulmonary diseases.

Changes in Death Rates

Table 1 illustrates the effect of an ongoing query program on cause-specific death rates. The principle result of querying is the reassignment of codes from less specific categories to more specific ones and from conditions that do not usually arise spontaneously to their underlying cause. Six of the 20 leading causes of death in Oregon had death rates which were more than 10 per cent higher or lower after querying. Although the overall death rates for some broad categories such as heart disease or malignant neoplasms changed little overall, the death rates by individual cause did change. For example, the rate for cardiac dysrhythmias declined 38.5 per cent, from 15.6 to 9.6 per 100,000 population, and malignant neoplasms of an unspecified site fell 28.1 per cent, from 8.9 to 6.4. At the same time, the rate for primary liver cancer increased from 0.8 to 1.7, a 112.5 per cent rise. Although the overall death rate for accidents fell 10.3 per cent, the rate for falls increased 8.9 per cent, from 5.6 to 6.1. Some other changes include: a 43.8 per cent decrease in deaths due to aspiration, a 46.2 per cent decrease in deaths attributed to an unspecified intestinal obstruction, a 90.9 per cent decrease in deaths due to motor vehicle traffic accidents of unspecified nature, a 16.7 per cent increase in deaths due to urinary tract infections, and a 30.3 per cent increase in deaths due to suicide with a specified firearm.

TABLE 1—Percentage Difference in the Death Rates of the 20 Leading Causes of Deaths before and after Querying, Oregon, August 1986–July 1987

Cause of Death	ICD Codes	Rate* Before	Rate* After	Per Cent Difference
Peptic Ulcer	531–533	2.3	3.0	+30.4
Alcoholic Disease	291, 303.0, 357.5, 425.5, 535.3, 571.0–571.3	9.4	11.8	+25.5
Hypertension	401, 403	3.7	4.2	+13.5
Other Diseases of Arteries	441–448	9.4	10.0	+6.4
Chronic Obstructive Pulmonary Diseases	490–496	42.6	44.7	+4.9
Diabetes Mellitus	250	12.6	13.2	+4.8
Arteriosclerosis	440	15.2	15.8	+3.9
Homicide	960–969	5.3	5.5	+3.8
Congenital Anomalies	740–759	5.3	5.5	+3.8
Malignant Neoplasms	140–208	198.8	202.8	+2.0
Early Infancy	760–779	5.1	5.2	+2.0
Cerebrovascular Disease	430–438	72.9	74.3	+1.9
Suicide	950–959	16.4	16.4	0
SIDS	798.0	4.2	4.2	0
Undetermined External Causes	980–989	1.6	1.6	0
Heart Disease	390–398, 402, 404.0–425.4, 425.6–429.9	296.6	295.9	−0.2
Influenza and Pneumonia	480–487	28.5	28.4	−0.4
Accidents	800–949	48.7	43.7	−10.3
Hernias and Intestinal Obstruction	550–553, 560	2.3	2.0	−13.0
Nephritis and Nephrosis	580–589	6.2	4.2	−32.3

*Rate per 100,000 population.

Because the OCHS has had a query program for many years, and consequently many physicians have learned how to complete a death certificate thoroughly and accurately, the effect demonstrated in Table 1 is very conservative. One measure of how quickly physicians learn to provide the necessary information is seen with the recently introduced tobacco use query. The OCHS initially requested that physicians note on death certificates the role of tobacco, if any, in the deaths of their patients. The request and rationale for this was presented in an article in the Oregon State Health Division's biweekly publication that is sent to all Oregon physicians. In the first three months, 60.0 per cent of the lung disease deaths were queried because the certifiers failed to note the role of tobacco. During the second quarter, the figure declined to 55.0 per cent, and by the third quarter only 34.0 per cent of the deaths required querying.

Survey of State Querying Practices

In the survey of other state vital statistics programs, twenty-one (40.4 per cent) of the registrars reported that their nosologists followed NCHS guidelines specifying the priority levels used. Four states responded they used the guidelines but gave vague answers as to the priority levels used. The four states (and their responses) are: Kansas (depends); Michigan (basic); New Jersey (as needed); Tennessee (partial). At least 23 states do not query at the minimum priority level, despite the fact that the NCHS has stated, "It is expected that every registration area will fulfill, as a minimum, all of the priority Level 1 requirements."[1] Some states, such as Rhode Island and Mississippi, did not report following NCHS guidelines, but appear to have thorough query programs and may be meeting these requirements.

Among those states following the NCHS guidelines, priority Level 1 was most often used (Figure 1). While registration areas using priority Levels 1–3 meet the NCHS minimum standard, Level 4 provides more comprehensive information. Levels 5 and 6 are "not necessary for general querying."[1] Oregon queries at Level 4, while four states—Colorado, Illinois, Kentucky, and South Carolina—reported using priority Level 5, the highest consistently used level. Colorado and Kentucky also occasionally use Level 6. Five states, then, reported querying at a comprehensive level. However, follow-up phone calls to states reported to query at Level 5 revealed that some do not query all the items within priority Level 5 or do so depending on workload.

Discussion

A query program can make a dramatic difference in the accuracy of cause-of-death data. Researchers comparing geographic differences in mortality should be aware of cause-of-death query programs and how these programs ultimately affect the data. For example, in 1984, the reported maternal death rate for the United States was 6.0 deaths per 100,000 live births.[5] The Oregon maternal death rate (13.6) during 1982–86 was 126.7 per cent higher than the national rate. These data suggest that a rigorous query program can substantially increase the reporting of deaths attributed to complications of pregnancy, childbirth, and the puerperium.

A computerized query tracking system allows the usefulness of responses to be monitored. Queries may be "fine-tuned" in this way to elicit better quality information and to measure the impact of rewording queries. Sometimes a change does not yield the expected improvement. For example, during August 1986 through January 1987 cardiac arrest had been queried with Form 1, "Was the underlying cause of the cardiac arrest known?" Over one-half (55.7 per cent) of 122 queries yielded information that resulted in a more specific underlying cause-of-death. In February, the query was reworded to "Some terminal events, such as cardiac or cardiopulmonary arrest, seldom arise spontaneously: Was there an underlying or more serious condition causing the cardiac or cardiopulmonary arrest?" This new phrasing resulted in only 37.3 per cent of the 107 queries with more specific causes of death. Additionally, 13.1 per cent of the physicians failed to respond to the new phrasing com-

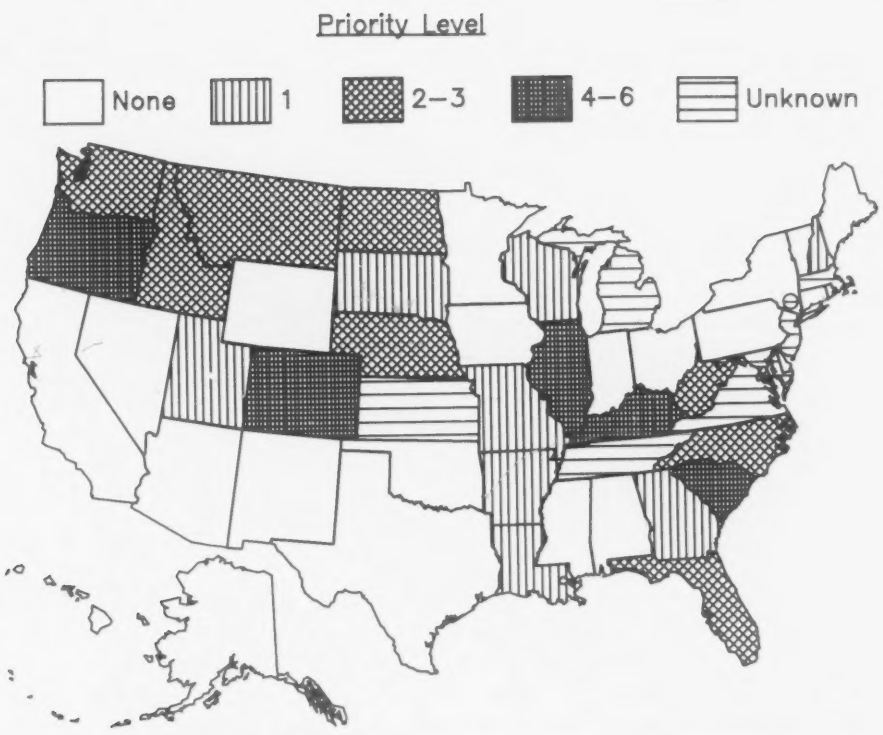

FIGURE 1—Survey Results of States' Querying Practices in Relation to NCHS Guidelines and the Priority Levels Used

pared to 5.7 per cent previously. Consequently, the previous form was reinstituted for this cause.

Unspecified liver disease and cirrhosis are priority Level 3 items under the NCHS guidelines. Data from states where death certificates are not queried at a level equivalent at least to priority Level 3 will not have as complete alcohol-related mortality data as areas which do query at this level. Only 10 states indicated on the survey forms that they consistently queried at least at priority Level 3 or for unspecified liver cirrhosis and disease. Four of these—Florida, Idaho, Kentucky, and Washington—during follow-up phone calls in June and July 1987, stated that they did not query for these causes, although they had listed Levels 3, 3, 5–6, and 3, respectively, on the survey form. Of the remaining six states, only three queried prior to the publication of NCHS guidelines to determine if cirrhosis or liver disease was alcohol-induced. The survey by phone included the question, "When did you begin to query liver cirrhosis and disease deaths to determine the role of alcohol?" Responses given were: Colorado, 1985; Illinois, 1985; Nebraska, at least 20 years ago; North Dakota, early 1970s; South Carolina, two to three years ago.

Because the OCHS has queried physicians about unspecified cirrhosis or disease of the liver since the early 1970s, many physicians report alcoholic or Laennec's cirrhosis without the necessity of a query. During 1986, 294 certificates were coded to 571.0–571.9. Most did not require querying because the decedent's liver disease or cirrhosis was noted to be alcoholic in origin (200) or because another cause was listed (22). Fifty-four certificates with ICD codes 571.5 and 571.8 were queried and all but nine (83 per cent) reassigned to 571.0–571.3. An additional 11 deaths were discovered to be due to alcoholic liver disease and cirrhosis from queries seeking unrelated information, while seven others were assigned to 571.4 and 571.8 for the same reason.

Oregon's query program has resulted in the state reporting the highest percentage of liver cirrhosis and disease deaths attributed to alcohol abuse. Nationally, 41.7 per cent of all liver disease and cirrhosis deaths in 1984 were listed as due to alcohol.** In Oregon 82.4 per cent were so classed, similar to the 83 and 85 per cent reported by Garceau.[6,7] Nonetheless, the overall liver cirrhosis and disease death rate was only marginally higher in Oregon than the US, 12.0 and 11.6 per 100,000 population, respectively. The apparent per capita alcohol consumption*** in Oregon (2.63) closely mirrors the national average (2.65).[8]

States whose vital statistics programs query at priority Level 4 or higher can be expected to have improved mortality data not only for alcohol-related deaths, but for all causes of death. While querying physicians in order to code and classify causes of death in accordance with ICD concepts, rubrics, and codes is just one step in the collection and dissemination of public health statistics, it is one that can, in certain instances, dramatically affect mortality data. Varia-

tion in cause-of-death querying between registration areas is one more factor that points to the need for a national program to periodically assess the quality of mortality data.[9] For mortality statistics to be of value as a national surveillance mechanism, it is important that data be collected in a standard and consistent manner. The NCHS recommendations, published only recently, may be adopted by more states as the benefits from establishing a query program are documented.

APPENDIX A
Causes of Death Suggestive of AIDS and Queried When AIDS is Not Mentioned on the Death Certificate

Atypical mycobacteria (*Mycobacterium avium* or *intracellulare*)
Bronchial, pulmonary or esophageal candidiasis
Chronic lymphoid interstitial pneumonitis
Cocciodioidomycosis
Cryptococcal meningitis
Cryptosporidiosis
Cytomegalovirus infection
Disseminated histoplasmosis
Hemophilia
Herpes virus infection
Immune deficiency
Immunoblastic sarcoma or lymphoma
Isosporiasis
Kaposi's sarcoma
Lymphoma limited to the brain
Non-Hodgkin's lymphoma in a person under age 60
Pneumocystic pneumonia
Pneumonia in a person between the ages of 1 to 50 and no clear alternative to AIDS as an explanation for the person's unusual susceptibility to pneumonia (i.e., leukemia, splenectomy)
Progressive multifocal leukocephalopathy
Salmonella (non-typhoid)
Small non-cleaved lymphoma (Burkitts' tumor or Burkitt-like lymphoma)
Stronglyloidosis
Toxoplasmosis
Tuberculosis in a person under age 60

Two Variants of Coronary Atherosclerosis in Six Populations

Richard E. Tracy, MD, PhD, Grace E. Kissling, PhD, and Margaret C. Oalmann, DrPH

Abstract: Coronary arteries and aortas obtained at autopsy in six populations were examined microscopically. Two variants of atherosclerosis could be separately quantified by objective morphometry. These two variants, fibroplasia and atheronecrosis, were both found to increase with age and to correlate with each other from one autopsy to the next after age adjustment. Despite the correlation of these two variables among individuals, the measures of fibroplasia and atheronecrosis did *not* correlate with each other across population groupings. A positive correlation of this kind between some populations was canceled by an inverse correlation between other populations. For example, Manila was the population with the greatest intimal fibroplasia in the coronary arteries at each age, and Sao Paulo was among those with the least intimal fibroplasia. Nevertheless, Sao Paulo showed the greatest tendency toward atheronecrosis, while Manila was among the populations with the least tendency toward atheronecrosis. The possibility arises, therefore, that the subjects from Sao Paulo were exposed to a different assortment of etiologic agents than were the subjects from Manila, and that their arteries, therefore, manifested a different kind of atherosclerosis. (*Am J Public Health* 1989; 79:575–581.)

Introduction

Atherosclerosis progresses throughout life from childhood precursors into eventually fatal complications in late life that affect coronary, cerebral, and other arteries. The rate of progression of atherosclerosis is thought to vary among human populations. The major basis for this belief is the International Atherosclerosis Project (IAP).[1] Vital statistics, clinical observations, and spotty reports of autopsy findings from nation to nation have consistently ranked some countries as high and others as low in the incidence and prevalence of atherosclerotic complications. An exact comparison of this kind, however, requires that representative samples of arteries from various sources be brought together in one place and objectively evaluated. This has been done twice: the World Health Organization (WHO)-sponsored five towns study,[2] and the IAP.[3] The WHO study found little difference among the five towns that they chose to compare; the least average percentage of surface affected by raised lesions being 30.6 in Yalta and the highest being 45.4 in Prague (standardized to age 55). The IAP compared arteries from populations which represent the extremes of known human experience; ranges were from 6 per cent in the Durban Bantus to 24 per cent in the New Orleans Whites (standardized to age 40).

The principal method used for measuring atherosclerosis in the IAP and in the WHO study was to assess by the unaided eye the extent of intimal surface judged to be affected by atherosclerotic lesions. This method was sufficient to show that: 1) raised lesions occur in the aortas and coronary arteries of all human populations, and 2) variations among populations are relatively small in comparison with variations among individuals within populations and between age groups. Therefore, the epidemiology of atherosclerosis requires rather large sample sizes to demonstrate the modest differences that prevail between populations. This method of gross inspection, however, was unable to probe the microscopic structure of aging arteries.

Two broad classes of raised atherosclerotic lesions are recognized microscopically, those with and those without necrotic cores.[4–6] These have been called "atheroma" and "preatheroma".[5] Microscopic examinations of aortas from the IAP archive have led to the suggestion that the pathogeneses and etiologies of these two classes of raised lesions are not the same in all populations.[7] Some populations such as Bogota residents and Durban Bantus were low on measures for both types of lesion while other populations, such as the Durban Indian, were high on both. On the other hand, the Sao Paulo, Brazil population, with the *greatest* tendency toward aortic lesions of the atheronecrotic type, was also among the populations with the least tendency toward the nonnecrotic, "fibroplastic" type. The population with the *least* tendency to atheronecrosis in that study of aortas, New Orleans Blacks, was also among the populations with the greatest tendency to fibroplasia. Those results raised the possibility that two separate processes, caused by different sets of etiologic agents, might be interacting in the arterial intima.

Microscopy is a little-used technology that offers unexplored new opportunities for seeking understanding of atherosclerosis epidemiology. The previous findings from the microscopic examination of aortas in eight populations are extended for this report to the coronary arteries in six populations.

Methods

Selection of Cases

The IAP, conducted in 1960-64, brought together in New Orleans about 23,000 sets of coronary arteries and aortas from 14 locations, five of them biracial, 19 location-race groups altogether.[1] In a previous study, aortas from eight of these populations were examined microscopically.[7] The eight groups chosen from the collection represent the extremes of observed arterial involvement by raised lesions and fatty streaks. Coronary arteries were available from the same cases which provided aortas in six of these groups: Durban, South Africa (Bantu and Indian); Bogota, Colombia; Mexico City, Mexico; Manila, Philippine Islands; and Sao Paulo, Brazil (Whites only).

A total of 395 specimens were successfully retrieved and prepared for microscopy, most of the failures being due to drying of the formalin used for storage. Numbers of cases by age, sex, population, and cause of death are given in the various tables.

Cause of Death Categories

Cases which clinically or at autopsy showed some atherosclerosis-related feature were classed as "Athero", all others

were called "Basal". Atherosclerosis-related features include hypertension, diabetes, myocardial scar or cerebral scar when observed incidentally, as well as overt causes of death such as myocardial infarct, stroke, or ruptured aneurysm.[10]

Processing of Tissues

Aortas and coronary arteries were previously opened longitudinally, formalin fixed, sudan stained, sealed in formalin-filled plastic bags, and stored in cardboard boxes containing stacks of 100 sets. Aortas were newly sampled along the left and right lateral walls from the 4th to the 12th intercostal ostia, as detailed elsewhere.[7] Right, left circumflex, and anterior descending coronary arteries were each cut into four segments of 2 cm length, some segments being absent in vessels shorter than 8 cm.[8] Longitudinally oriented segments were decalcified with acetic acid, blocked in paraffin, sectioned at 11 μm, and stained with hematoxylin-eosin. Ink marks were placed on the cover slips to define one centimeter intervals on the coronaries, and at intervals in the aorta to define 1/20 of the sample length—approximately 0.7 cm in most aortas. Up to 27 marked positions were evaluated in the coronaries and up to 40 in the aortas.

Evaluation of Slides

Positions affected by atheronecrosis, operationally defined as having cholesterol clefts easily discerned under the 40x objective lens, were marked with black ink; the percentage of the length of the specimen marked positive for atheronecrosis was called P_{Aa} for the aorta and P_{Ac} for the coronaries. The mean thickness of the intima (μm), averaged over the nonnecrotic points, were called F_c for coronaries and F_a for aortas. Details of these methods are discussed elsewhere.[8]

Statistical Strategy

The outcome measures for the two types of atherosclerotic lesions in the two arterial segments, P_{Aa}, P_{Ac}, F_a, and F_c, were found to correlate with age and with each other from one case to another. Variation of these measures among populations was therefore examined after age adjustment. To test if the age adjustment was equally appropriate to all populations, the adjusted values of F were compared separately for the ages over and under 30 years. This could not be done for P_A, because this measure is nearly always zero below age 30. Next, the residual variation of P_A among populations was examined after adjustment for its correlation with F; this adjustment was improved by taking the square root of P_A.[9] The analyses were done separately for two broad cause of death groups to examine the effect of inequalities among the autopsy samples in their cause of death compositions. The statistical details of the analyses are reported in the Appendix.

Results

The average nonnecrotic intimal thickness, i.e., *fibroplasia*, tended to rise with age, as shown in Figure 1. Perhaps the most striking feature of the scatter plot is the great variation among individuals who are alike in age. However, the average trend, as shown by the curve representing equation (1) is clearly upward with age.

Atheronecrosis tended to affect the older cases and those with the greatest intimal fibroplasia, irrespective of cause of death category. In Figure 1, the open circles, representing specimens *with* atheronecrosis, are upward and rightward of the closed circles representing specimens *without* atheronecrosis. The dashed curve in Figure 1 represents the optimal separation between the open and closed circles, as given by equation (2). The curve helps to emphasize the finding that

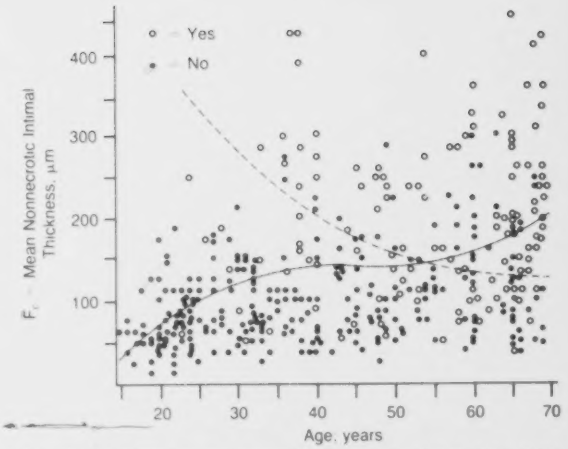

FIGURE 1—All 395 cases are represented, using open symbols to designate the 132 cases with at least one instance of atheronecrosis in the coronary arteries. The solid curve represents the cubic regression equation (1). The dashed curve represents the logistic regression equation (2) with log odds = 0, which optimally separates the open from the closed circles.

elderly subjects can manifest atheronecrosis at lesser degrees of fibroplasia than is required in youth.

Variation of Fibroplasia among Populations

Some of the variation among individuals seen in Figure 1 is due to population membership, because populations were not all alike in fibroplasia. Manila was the population with the greatest intimal thicknesses at each age in the coronary arteries and Sao Paulo was among those with the least. As shown in the scatter plot of Figure 2, 58 of the 74 specimens of coronary arteries from Manila are above the age-adjustment regression line. From Sao Paulo, 12 of the 69 specimens are above the line.

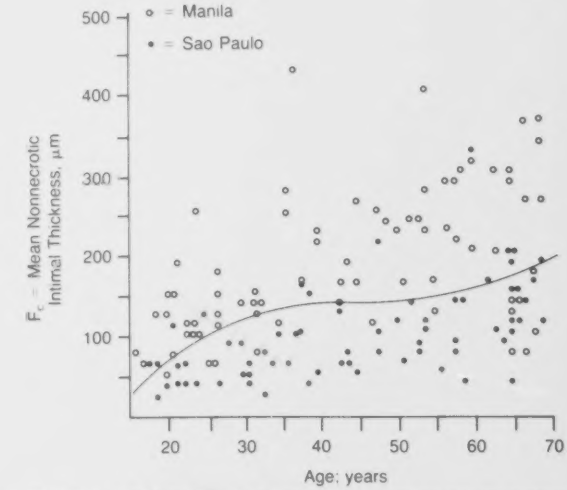

FIGURE 2—Manila and Sao Paulo illustrate the populations with the extremes of high and low fibroplasia observed in the intima of coronary arteries at each age. The curve represents the cubic regression equation (1).

*Adjusted to age 45 through the regression equations (1) and (1a).
**Results of 2-Way analysis of variance, F-Value (Pr>F), are from PROC GLM of the SAS package carried out upon the residuals from the cubic regression equations.

The population differences persisted after age adjustment (Table 1) by regression equations explained in the Appendix. This analysis retains the distinction between cause of death groupings to show that atherosclerosis-related causes did not greatly distort the pattern of variation among populations as seen in the basal cases only. Cause and population differences were present for the coronary arteries as well as the aortas. Manila was consistently ranked first or second, and Sao Paulo fourth, fifth, or sixth for aortas and coronary arteries of both cause of death groupings.

In Figure 2, the specimens from Manila seem to show greater fibroplasia than those from Sao Paulo even at ages less than 30 years. This result was confirmed by ANOVA in Table 2. Intimal fibroplasia of the coronary arteries in the six populations before and after age 30 showed a rank correlation of 0.99. The comparable correlation for the aortas is 0.72. The age-adjusted fibroplasia analyzed in Table 2 showed no differences between groups over and under age 30, suggesting that the age adjustment is equally appropriate to all six populations.

Variation of Atheronecrosis among Populations

The six populations differed from each other in raw measures of the percentage of atheronecrosis in the coronary arteries (Figure 3). As seen in the diagram, the differences among populations in atheronecrosis seem independent of the variation in fibroplasia. We have already seen, however, that specimens with more fibroplasia are, for each age, at greater risk of showing atheronecrosis (Figure 1, equations (2), (3), (3a)). It seems fair to ask, therefore, if the amounts of atheronecrosis observed in each population might be commensurate with the degrees of fibroplasia, after appropriate age adjustment. Manila, for example, had the greatest fibroplasia, while Sao Paulo had nearly the least; therefore, according to equation (3), these populations should be respectively among the greatest and the least affected by atheronecrosis. The reverse outcome was actually observed, as given in Table 3. Sao Paulo had the *most* atheronecrosis, after adjustment for age and fibroplasia and Manila was among the populations with the least atheronecrosis (adjusted); the respective means ± SEMs were 1.97 ± 0.22 and 0.70 ± 0.18 square rooted percentage units. In a graphic presentation of these results, Figure 4, the line representing equation (3) is plotted, and departures from that line represent the residuals used in the ANOVA of Table 3. The two populations had equal numbers of non-zero specimens, 32 out of 74 for Manila and 32 out of 69 for Sao Paulo, despite the fact that the risk functions from equations (3) and (3a) predict greater risk in Manila. In Figure 4, 30 of the 32 non-zero specimens from Sao Paulo have values for atheronecrosis

TABLE 2—Age-Adjusted Mean Nonnecrotic Intimal Thickness* (μm) by Arterial Segment and Age for Six Populations

**Age adjustments and ANOVA as in Table 1. The purpose of doing this analysis on the age-adjusted variable is to test if the same age adjustment is appropriate to all six populations.

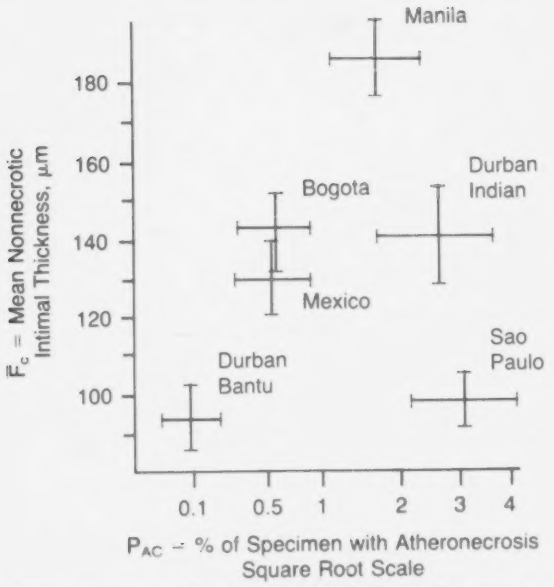

FIGURE 3—The means, plus or minus one standard error of the mean, are represented for each of the 6 populations. Fibroplasia and atheronecrosis values plotted here are not age-adjusted or otherwise adjusted.

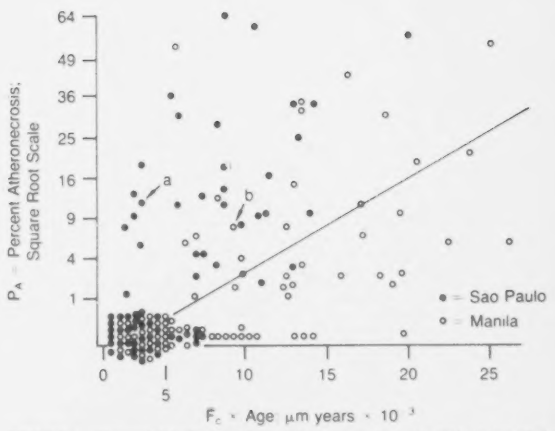

FIGURE 4—The variable obtained by multiplying age times fibroplasia is plotted against atheronecrosis, on a square root scale, for the two populations which differed most on plots of this kind. The product variable, fibroplasia-years, was especially interesting because of its importance in equations (3) and (3a). The cases marked "a" and "b" were near the centers of the scatters for *young* persons in the two populations, and were therefore considered to be "typical"; they are illustrated photographically in Figure 5.

that are above the regression line, compared with 15 of those from Manila. The six populations were not ranked the same on measures of fibroplasia and atheronecrosis (adjusted) (rank r = −0.03).

Photographic Examples

Two cases were chosen to illustrate photographically the contrast between typical appearances in Sao Paulo and Manila in Figure 5. Case "a" from Sao Paulo had age = 34, F_c = 62, and P_{Ac} = 9.4. Case "b" from Manila had age = 44, F_c = 192, and P_{Ac} = 8.0. These two cases are typical because of having values that are near the average for subjects in their respective populations. The photographs illustrate that nonnecrotic intimal thickness is less in Sao Paulo than in Manila, yet atheronecrosis can unexpectedly exist in this less thickened fibroplastic intima.

Attrition of the Sample

Specimens from 10 males and 10 females were drawn from the archive in each of the six 10-year age groups, making 120 for each of the six populations. Forty-five per cent of the specimens were found to be unsuitable for histology; these had been improperly dissected, fixed, or stored, the major cause of attrition being drying during storage. By Chi-Square test, the attrition of specimens appeared to be randomly distributed among the six populations. However, the population with the thickest specimens, Manila, had the least attrition (46) while the population with the thinnest specimens, Durban Bantu, had the most attrition (64), and the rank correlation in this regard was statistically significant (r = 0.829, Table 4). It seems likely that the thinnest specimens are most prone to being ruined by improper storage. How this

*Adjusted to age 45 and to intimal thickness of 135 μm (Coronaries) or 240 μm (Aortas) through the regression equations (3) and (3a)

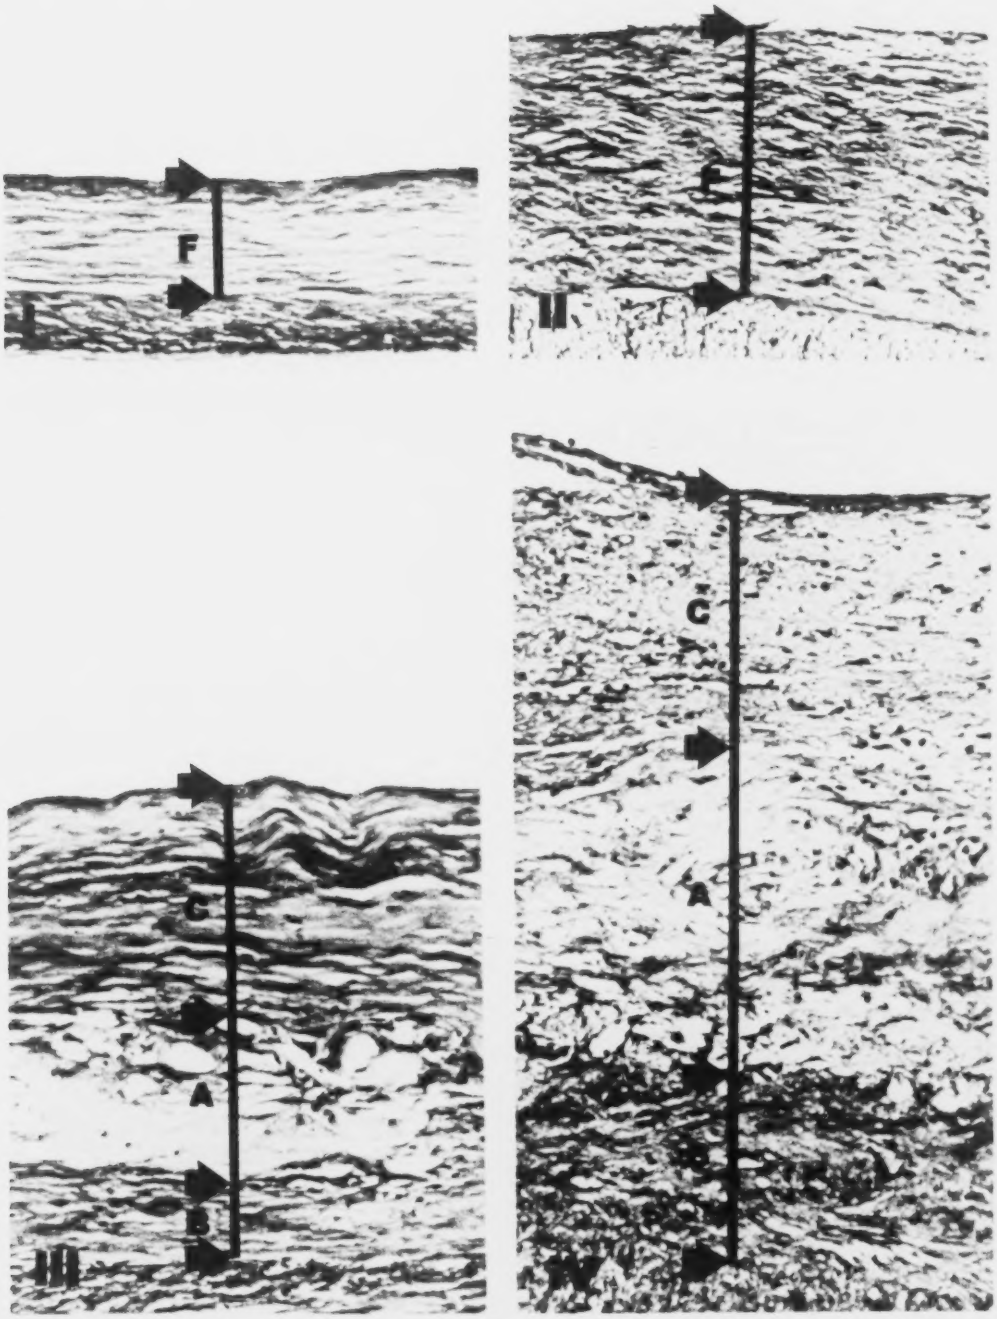

FIGURE 5—Coronary arteries of the two cases marked "a" and "b" in Figure 4 are illustrated in frames I and III and frames II and IV, respectively. Frame I shows nonnecrotic intimal thickness of 80 μm (F) which was near the average for this case and for Sao Paulo males of age 45. Frame II shows thickness of 185 μm which is near average for this case and for Manila males of age 45. Frames III and IV show necrotic cores (A) accompanied by "threshold" amounts of fibroplasia formed from the sum of the fibrous cap (C) and base (B). B + C = 200 μm in the Sao Paulo case of Frame III and 300 μm in the Manila case of Frame IV, amounts which are near average for 45 year old males in those two populations. Hematoxylin-eosin, X280.

selection bias might affect the results is hard to assess, but is apt to be small.

Discussion

Atheronecrosis is generally believed to be a late complication that sometimes intrudes upon fibroplastic, "preatheromatous", intimal thickening. This viewpoint might look upon equation (3) not just as an empirical description of an observed correlation, but as a model of a real process evolving in time. This viewpoint was recently elaborated in some detail.[8] It is not necessary, however, to accept this theory in order to pursue the epidemiology of the tissue abnormalities. Manila was observed in the data reported here to have a greater tendency toward fibroplasia than Sao Paulo but a lesser tendency for the thickened and aged intima to show atheronecrosis. Since "the cause" of atherosclerosis is multifactorial, the subjects from Sao Paulo may have been exposed to a different assortment of etiologic agents than were the subjects from Manila, and therefore their arteries manifested a different kind of atherosclerosis.

A potential selection bias which could, in theory, bear upon the observed outcome is the so called "Berkson fallacy."[10] If two populations differ in death rates or autopsy rates for certain kinds of causes, such as malnutrition, infections, etc., then the two series of autopsies could reveal spurious differences in atherosclerosis; this is because subjects with coronary heart disease might comprise most of the autopsies in one place but not the other. This possibility seems an unlikely explanation for the differences between populations reported here, because the same pattern of population contrasts was seen in both of the cause-specific groups of autopsies. Manila had the greatest fibroplasia in both basal and atherosclerosis-related cause of death groups, while Sao Paulo ranked fifth or sixth in both cause groups (Table 1). The two populations reversed their relative positions when looking at atheronecrosis instead of fibroplasia, and this reversal was seen equally well in both cause of death groups (Table 3). Indeed, the contrasts between populations seem somewhat greater in the atherosclerosis-related than in the basal groups, as if death from one kind of atherosclerosis might cut short the progression of the other kind. The same result was previously seen in the aortas.[7]

Another kind of selection bias must also be considered. These speculations do not necessarily apply to the general populations in Brazil or the Philippines, or elsewhere. To what extent the particular racial and cultural group samples studied here might be representative of the source cities or countries constitute questions that are newly raised by the findings. Without knowing whether these cases were sampled from populations which are representative of their nations of origin, it is still possible to conclude that fibroplasia and atheronecrosis do not always travel together across population boundaries. This is a newly discovered principle, previously seen in the aortas, but, for the coronary arteries reported here for the first time. The matter requires further verification before general acceptance.

A dissociation between fibroplasia and atheronecrosis has been noted in some experimental situations. For instance, rabbits showed fibroplastic intimal responses to feeding peanut and coconut oils, atheromatous reactions to butter fat, and little of either result from corn oil.[11] It could be no more than coincidence that the arteries from a land of coconut oil consumption, Manila,[12] had a resemblance to those of rabbits fed oil of coconuts, or that arteries from a land of cottonseed and soya oil consumption, Sao Paulo,[12] resemble those of rabbits fed butter. The experimental data, however, do help to validate the suggestion found in these human data that atherosclerosis may be a composite result of two separate processes interacting in the same tissue. This matter has been raised into serious consideration by the findings reported here, because comparisons of arteries from different human populations showed an effect similar to that previously known only for experimental settings. The next step, which is to correlate the two kinds of atherosclerosis with putative etiologic agents, will require further comparisons of human populations.

APPENDIX

Quantitative variables measured upon two cause of death classes in six populations lend themselves to multivariate statistical analysis. The SAS package of programs, version 5, was used.

Fibroplasia in the coronary arteries of 395 cases were related to age by a cubic regression equation with all coefficients statistically significant

$$F_c = 0.003{,}12\ A^3 - 0.417\ A^2 + 19.2\ A - 168 \quad (R^2 = 0.154), \qquad (1)$$

where F_c is fibroplasia in the coronary arteries, measured in micrometers, averaged over all of the points observed in a specimen, and A is age in years. All coefficients are significant at $\alpha = 0.05$. The curve representing this equation is drawn in Figures 1 and 2. The linear correlation, with $R^2 = 0.142$, is not greatly inferior to the cubic, and might suffice for age adjustment. Nevertheless, differences in age structure among the populations are apt to be better compensated by the cubic, and the equation (1) is therefore used.

For the aortas, the higher order terms in the cubic regression were not statistically significant ($\alpha = 0.1$), and were therefore not retained. For age adjustment of fibroplasia measures in the aorta (F_a),

$$F_a = 5.34\ A + 1.45 \quad (R^2 = 0.304) \qquad (1a)$$

Residuals from equations (1) and (1a) were examined by ANOVA in Tables 1 and 2.

Atheronecrosis can be treated as a quantitative variable, expressed as the percentage of affected specimen (P_{Ac} and P_{Aa} for coronary artery and aorta respectively), or as a categorical variable, each specimen treated as having or not having at least one instance of atheronecrosis. Setting odds equal to the ratio of affected to not affected specimens, logistic regression yielded

$$\text{Log odds} = 0.000{,}304\ F_c \cdot A - 2.80 \quad (\chi^2 = 103.9) \qquad (2)$$

This function correctly classifies 79.3 per cent of cases, and the χ^2 of 103.9 refers to the 2×2 classification table. This equation, with log odds = 0, is plotted in Figure 1. The linear terms in F_c and A were rejected as not statistically significant. By multiple linear regression

$$\sqrt{P_{Ac}} = 0.000{,}211\ F_c \cdot A - 0.254 \quad (R^2 = 0.354) \qquad (3)$$

Again, the linear terms were not significant. For the aorta, the linear term on age was retained because it was significant,

$$\sqrt{P_{Aa}} = 0.000{,}164\ F_a \cdot A - 0.030{,}3A + 0.35 \quad (R^2 = 0.542) \qquad (3a)$$

Residuals from equations (3) and (3a) are examined by ANOVA in Table 3.

Survey Shows HIV Reporting Practices in 50 States

A national survey of HIV reporting requirements in all 50 states and the District of Columbia—conducted by the AIDS Policy Center of the Intergovernmental Health Policy Project at George Washington University—shows that anonymous testing, in some form, is available in more than four-fifths of the states. The results demonstrate a clear trend to maintain public access to anonymous testing while ensuring that health officials have access to test recipients' names under certain conditions.

In most states, the system reflects the efforts of public health officials to balance various needs, including privacy and confidentiality, risk-reduction education, follow-up care, intervention, and monitoring spread of the disease.

According to the survey, state reporting systems fall into five major categories based on whether those who test positive for HIV must be reported to state or local health officials. The categories are: 1) confidential reporting (where names must be reported); 2) confidential reporting, with some anonymous testing available; 3) anonymous testing with names required in specific instances; 4) anonymous reporting, where aggregate or demographic data must be reported or where individuals' test results must be reported, without names or identifiers; and 5) anonymous testing where no names or individual information is reported.

Findings of the survey indicate that:

- only eight jurisdictions require names to be reported as a matter of policy or law;
- 10 states have retained their anonymous test sites without mandating other reporting requirements;
- a dozen states either require aggregate reporting of seropositive patients (without names) or allow codes to be used in lieu of names;
- six states have determined that HIV reporting should remain basically anonymous with a few mandated exceptions, such as name reporting of seropositive infants and persons who indicate they will not notify their own sexual contacts;
- some states that have mandated confidential testing only (by name) are moving to an anonymous testing system.

The AIDS Policy Center is an AIDS legislative and policy research center that provides AIDS information and related research to legislators, policy-makers, and the media. In addition to publishing monographs on a variety of topics including state AIDS legislation, state AIDS funding, and general AIDS policy, the Center publishes a regular newsletter, *State AIDS Reports*.

Hypertension in Israeli Adolescents: Prevalence According to Weight, Sex and Parental Origin

MORDECHAI SHOHAT, MD, TAMAR SHOHAT, MD, MARC MIMOUNI, MD, MENACHEM NITZAN, MD, AND YEHUDA L. DANON, MD

Abstract: We studied the prevalence of hypertension in 57,499 male and 35,803 female Israeli military recruits and its relation with sex, weight, and parents' ethnic origin. The overall prevalence of systolic hypertension (>140 mmHg) was 1.75 per cent for males and 0.32 per cent for females. The prevalence of diastolic hypertension (>90 mmHg) was 0.41 per cent for males and 0.06 per cent for females. For males, the prevalence of systolic and diastolic hypertension increased with weight, exponentially. Males of Ashkenazi origin had a significantly higher prevalence of hypertension (systolic 2.52 per cent, diastolic 0.55 per cent) compared with those of Sephardi origin (systolic 1.12 per cent, diastolic 0.3 per cent). The prevalence of adolescents with systolic or diastolic blood pressure greater than the mean +2SD of each weight group ranged between 1.5–2.3 per cent. (*Am J Public Health* 1989; 79:582–585.)

Introduction

The prevalence of hypertension reported from different parts of the world ranges from 1 to 20 per cent of the adolescent population.[1] We report here the low prevalence among Israeli adolescents and the relation of hypertension to weight, parents' ethnic origin, and sex.

Methods

The National Service Act requires all Israeli boys and girls to present themselves at the age of 17 years at the induction centers for the purpose of classification for military service. Arab boys and girls are exempt from service and are not routinely examined in this system. Other exclusions are comprised mainly of girls who declare themselves to belong to orthodox religions (a proportion that dropped from 32 per cent in 1977 to 24 per cent in 1985)[2] and both boys and girls who are severely mentally retarded or handicapped. Ninety-four per cent of the boys born in 1966 underwent a complete physical examination at the age of 17 years and received a health classification score before the end of 1985.[3] Other characteristics of the population seen in the induction centers, the examinations, studies performed, and classification system are described in detail elsewhere.[3]

We analyzed the military recruit medical records of 58,499 healthy males (25,782 of Ashkenazi origin; 31,717 of non Ashkenazi [Sephardi] origin) and 35,803 healthy females (14,678 Ashkenazi; 21,125 Sephardi) who underwent a complete physical examination at the age of 17 years as part of a routine health assessment in the induction centers during a certain period of time between 1980 and 1986. Adolescents older than 17 years of age at the time of examination were not included in the study.

Blood pressure (BP) was taken once during the morning, using a mercury gravity sphygmomanometer (Baumanometer, W.A. Baum Company Inc., New York) with a standard adult cuff (bladder width 13 cm and length 24 cm) after the participant had been seated at least 5 minutes. All the measurements for blood pressure were taken by physicians. Weights were measured by the physicians in males and by trained soldiers in females. Weight was recorded to the nearest kilogram with the subject wearing only underwear. The physicians were instructed to determine the systolic blood pressure (SBP) and diastolic blood pressure (DBP) as the first and fifth phase korotkoff's sounds, respectively. During the next three to six months, adolescents with systolic blood pressure (SBP) exceeding 140 mmHg or diastolic blood pressure (DBP) 90 mmHg underwent five additional BP measurements on different days under simulated basal conditions (in the individual's family physician's office after the participant had been seated at least 5 minutes) and the mean of these measurements was recorded. Only those with a measurement mean pressure exceeding 140 mmHg systolic or 90 mmHg diastolic were considered hypertensive.[4]

After determining the prevalence of SBP and DBP for each sex according to parents' ethnic origin, we restricted our analysis to males weighing 46–90 kgs and females weighing 46–80 kgs. This selection included 95 per cent of the total recruit population of each sex and was aimed at preventing errors resulting from inappropriate cuff size. Data were classified by 5 kg subgroups and analyzed according to sex and parental ethnic origin.

Results

The crude prevalence of systolic hypertension (Table 1) was 1.75 per cent for males and 0.32 per cent for females, for diastolic hypertension, 0.41 per cent for males and 0.06 per cent for females. Males of Ashkenazi origin had a systolic prevalence of 2.52 per cent, diastolic 0.55 per cent, compared to a systolic prevalence of 1.12 per cent, diastolic 0.3 per cent

TABLE 1—Prevalence of Systolic (SBP > 140 mmHg) and Diastolic (DBP > 90 mmHg) Hypertension According to Sex and Ethnic Groups

	Ethnic Groups		
	% Ashkenazi	% Sephardi	% Total
Males			
SBP > 140 mmHg	2.52	1.12	1.75
DBP > 90 mmHg	0.55	0.30	0.41
Females			
SBP > 140 mmHg	0.35	0.32	0.32
DBP > 90 mmHg	0.11	0.09	0.10

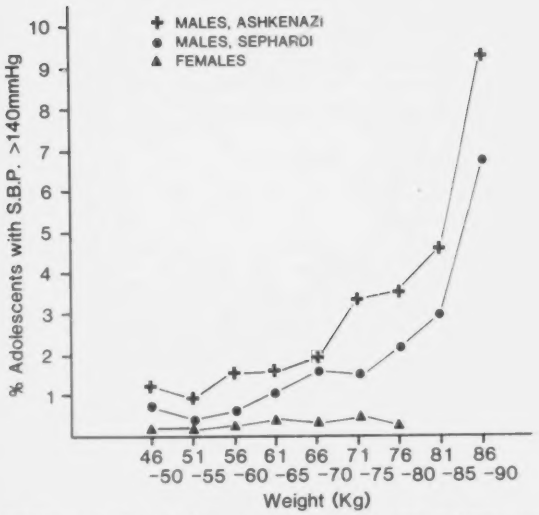

FIGURE 1—Per Cent of Adolescents (weighing 46–90 kg) Who Had SBP > 140 mmHg According to Weight Subgroups (values according to parental ethnic origin for the females were almost the same)

for those of Sephardi origin. The corresponding figure for females are Ashkenazi: systolic 0.35 per cent, diastolic 0.11 per cent; Sephardi: systolic 0.32 per cent, diastolic 0.09 per cent.

Figures 1 and 2 depict the per cent of adolescents (weighing 46–90 kg) who had SBP >140 mmHg and DBP >90 mmHg, respectively, according to weight subgroups and parental ethnic origin. Since the prevalence of both systolic and diastolic hypertension for females of both parental ethnic origins was similar in all weight groups, a single line depicts the mean values of the Ashkenazi and Sephardi female

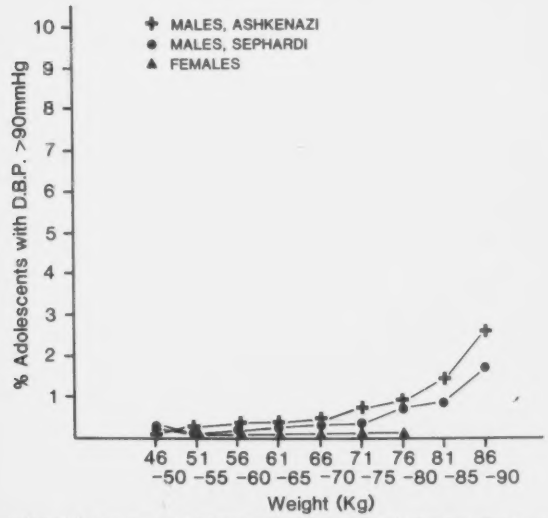

FIGURE 2—Per Cent of Adolescents (weighing 46–90 kg) Who Had DBP > 90 mmHg According to Weight Subgroups (values according to parental origin for the females were almost the same)

groups. For males overall, the prevalence of diastolic hypertension and systolic hypertension increased with weight exponentially. Controlling for comparable groups, systolic prevalences are higher in males than in females and higher in males of Ashkenazi origin than in those of Sephardi origin (Figure 1). Differences according to parental ethnic origin for the DBP (Figure 2) are less prominent.

Figures 3 and 4 depict the mean blood pressure values ±2SD for SBP and DBP, respectively, according to weight groups and parental ethnic origin. Diastolic blood pressures in females of both parental ethnic groups (Figure 3) were not significantly different in any of the weight groups and therefore Ashkenazi and Sephardi females are presented by a single (mean) line.

Discussion

Recently, a National Institutes of Health Task Force report presented guidelines for detecting high BP in children.[4,5] High BP or hypertension is defined as systolic and/or diastolic BP equal to or greater than the 95th percentile for age and sex on at least three occasions. For 17 year old male adolescents (WT: 84 kg), the cutoff points are 141 mmHg systolic and 91 mmHg diastolic, both of which are 1 mmHg higher than our definitions. The changes of BP

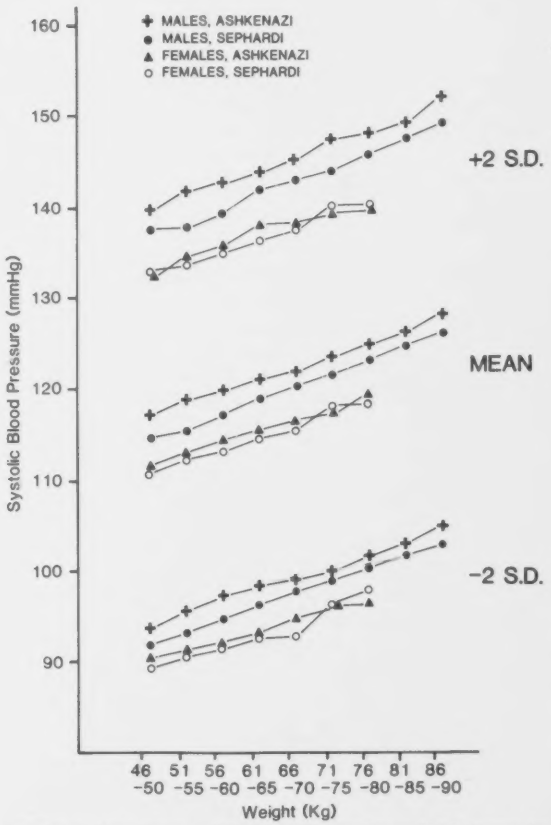

FIGURE 3—Mean Values + 2SD of the SBP According to Weight Groups for each Sex and Parental Origin

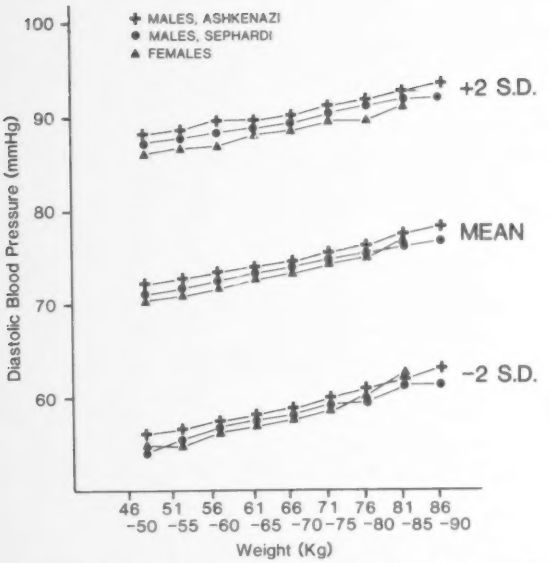

FIGURE 4—Mean Values +2SD of the DBP According to Weight Groups for each Sex and Parental Ethnic Origin (females of both parental ethnic origins are represented together as their values were almost identical)

according to weight in the adolescent group were not addressed in the report. The mean systolic and diastolic BP for males and females in our study was 3–5 mmHg higher than the new BP standards for adolescents of comparable weight. Our findings compare favorably with levels reported from South Carolina.[6] Nevertheless, the prevalence of hypertension was relatively low.

The true prevalence of hypertension in children and adolescents is not yet known. In his summary of the prevalence of hypertension reported from 13 regions in the world, Loggie[1] found that it ranged from 1 to 20.5 per cent. In studies using a definition of hypertension comparable to ours (SBP >140 mmHg, DBP >90 mmHg), the prevalence ranged from 1.4 to 11 per cent. Most of the studies reported are cross-sectional and repeat screening of those identified initially as "suspect hypertensive" is only infrequently reported.[1] Kilcoyne, *et al*,[7] and Reichman, *et al*,[8] who reported re-screening in New York City, found that significantly fewer "hypertensives" remained "hypertensive" at a second examination. Therefore, the fact that hypertension was defined in our study as the mean of five recurrent measurements on different days, under basal conditions, may explain the low prevalence of hypertension found in our study. Since the basal pressure in adolescents and young adults is a better predictor of hypertension in adulthood than "causal" BP,[9,10] it seems that the prevalence found in our study is closer to the actual prevalence of hypertension in adolescence. Since the causes for hypertension were not explored, the figures found represent the prevalence of hypertension, suggesting that essential hypertension is even less prevalent in our studied population. In adolescents who were under treatment for hypertension at the time of initial examination, blood pressure was determined under treatment. Although this might underestimate the blood pressure readings in those individuals, it probably changed the findings very little, since only a small number of adolescents (<0.02 per cent) were under such a treatment. It is possible that difficulties in excluding people from military service because of blood pressure elevations influenced the observing physicians to report lower readings and, therefore, reduced the prevalence of hypertension in our study. Nevertheless, since that bias in blood pressure measurement should not differ between ethnic groups and weight groups, cross-sectional comparison of distribution and mean values probably does reflect underlying ethnic differences.[3]

The American Heart Association committee recommends standardization of the bladder size in the sphymomanometer cuff.[11] For adolescents with arm circumference of 23–32 cm (equivalent to 46–90 kg of weight in the study and in other investigations), the standard adult cuff (13×24 cm) caused no more than a mean error of 5 per cent in the indirect blood pressure measurement.[12] BP measurement in our study suggests that there is an exponential increment in the prevalence of hypertension with increased weight in males regardless of parents' ethnic origin. The prevalence of systolic and diastolic hypertension among males weighing 86–90 kg is about 8–11 times greater than among males weighing 51–55 kg. For females, this increment seems to be less prominent. A positive correlation between hypertension and weight during childhood has been reported by other investigators.[13,14] This finding focuses on a major problem concerning the definition of hypertension. By what criteria should hypertension be defined? Should the fixed level (as in our study) be used or is it necessary to use specific percentiles (>97 per cent) for each weight group? In our population, the latter criteria would designate 1.5–2.3 per cent of the children as "hypertensive" for every weight between 46–90 kg.

Males of Ashkenazi origin have higher BP than those of Sephardi origin in almost all weight groups. As for females, this difference was less impressive. Several studies in Israel have shown ethnic differences in coronary heart disease (higher in Ashkenazi) as well as in other genetic characteristics such as blood groups and protein-enzymatic markers; these were reviewed recently by Goldbourt and Neufeld.[15] According to information from the Israeli Bureau of Statistics, the socioeconomic status of the Ashkenazi population is higher than the Sephardi whose diet is rich in salt. Adolescents of Ashkenazi origin are taller and heavier in comparison to those of Sephardi origin[16]; however, the differences in BP remained even after controlling for weight. Therefore, genetic factors may better explain this finding. A higher BP was obtained in American Black children and adolescents in comparison to Whites.[7,17] In order to decide if the same definition should be used for all races, it seems important to determine whether the prognosis of essential hypertension is the same.

AMSA Launches National Program to Teach Adolescents How to Resist Drugs, Peer Pressure

In response to concern over increasing drug use in the teen years and even earlier, the American Medical Student Association (AMSA) announced in late March the nation's first program that uses medical students to teach adolescents to resist peer pressure for alcohol and drug use.

Funded by the Office for Substance Abuse Prevention, US Department of Health and Human Services, AMSA's Substance Abuse Prevention program has trained medical students to provide prevention services to approximately 8,000 adolescents in grades four through eight. Between 150 and 200 students from eight or nine medical schools across the country have assessed the educational and personal needs of the teens and preteens in their local communities in order to design and conduct effective programs.

AMSA's President, Dr. Cindy Osman, noted the high probability that this program will have a profound effect on adolescents across the country. "This idea can work," she said. "We know that children and teenagers are most receptive when they learn from role models whom they respect. Young physicians can be powerful role models and we think they can get to kids before they begin to experiment."

Upon completion of the project, the American Medical Student Association will create educational materials which can be used in the classroom and other community settings for substance abuse prevention education.

The eight participating medical schools thus far include:
Brown University Program in Medicine, Providence, RI
George Washington School of Medicine, Washington, DC
Hahnemann University School of Medicine, Philadelphia, PA
University of South Florida College of Medicine, Tampa, FL
Louisiana State University School of Medicine, New Orleans, LA
Wayne State University School of Medicine, Detroit, MI
Washington University School of Medicine, St. Louis, MO
College of Osteopathic Medicine of the Pacific, Pomona, CA

Results of Routine Restaurant Inspections Can Predict Outbreaks of Foodborne Illness: The Seattle-King County Experience

KATHLEEN IRWIN, MD, JANE BALLARD, MS, JOHN GRENDON, DVM, MPH, AND JOHN KOBAYASHI, MD, MPH

Abstract: To analyze the association between the results of routine inspections and foodborne outbreaks in restaurants, we conducted a matched case-control study using available data from Seattle-King County, Washington. Case restaurants were facilities with a reported foodborne outbreak between January 1, 1986 and March 31, 1987 (N=28). Two control restaurants with no reported outbreaks during this period were matched to each case restaurant on county health district and date of routine inspection (N=56). Data from the routine inspection that preceded the outbreak (for case-restaurants) or the date-matched routine inspection (for control restaurants) were abstracted from computerized inspection records. Case restaurants had a significantly lower mean inspection score (83.8 on a 0 to 100 point scale) than control restaurants (90.9). Restaurants with poor inspection scores and violations of proper temperature controls of potentially hazardous foods were, respectively, five and ten times more likely to have outbreaks than restaurants with better results. Although this study demonstrates that Seattle-King County's routine inspection form can successfully identify restaurants at increased risk of foodborne outbreaks, it also illustrates that more emphasis on regulation and education is needed to prevent outbreaks in restaurants with poor inspection results. (*Am J Public Health* 1989; 79:586–596.)

Introduction

Routine inspection of restaurants to prevent foodborne disease is mandated by food sanitation codes throughout the United States[1] and is recommended by the Model Standards for Community Health Practice of the US Public Health Service.[2] Although common sense dictates that the results of routine inspections should predict outbreaks of foodborne illness, this relation has never been studied in food service facilities other than cruise ships.[3] We therefore conducted a case-control study to determine whether routine inspection results and other characteristics were associated with reported foodborne outbreaks in restaurants using available data from Seattle-King County, Washington.

Restaurant Permit Program

For several decades, the Seattle-King County Department of Public Health has issued annual permits for permanent restaurants. Since January 1, 1986, when 3,076 restaurants had such permits,* characteristics noted on the permit have been entered into a computerized permit file.[4]

Restaurant Inspection Program

Sanitarians in five health districts use a standard reporting form developed by the Seattle-King County Department of Public Health for all routine inspections.[5] Data from the current form have been entered into a computerized inspection file since the form was adopted on January 1, 1986. The form identifies 42 types of violations classified as "critical" or "noncritical." Critical violations are thought to have a direct impact on foodborne disease, e.g., the temperature of potentially hazardous foods, food handling practices, the health status of food handlers (Table 1). Noncritical items are thought to play a minor role in foodborne illness, e.g., the cleanliness of nonfood contact surfaces, walls, and ceilings. A critical violation incurs a debit of 4-5 points from a perfect inspection score of 100, whereas a noncritical violation incurs a debit of 1-2 points. Violations are also classified as to type (food, food protection, personnel). After tallying all debit points, sanitarians assign a final score from 0 to 100 and a result category, which is largely a function of the final score. A score of 86 to 100 indicates a "satisfactory" result. A score of 70 to 85 or a violation of any critical item indicates an "unsatisfactory" result, requiring timely correction of violations. A score of less than 70 points indicates a "suspend permit" result, warranting permit suspension and restaurant closure. These score cutoffs were based on a county-wide study that simultaneously scored restaurants with the old 298-point inspection form and the new 100-point form; restaurants closed on the basis of the old form typically received scores of less than 70 on the new form.*

Foodborne Illness Investigations

Epidemiologists in the Seattle-King County Department of Public Health receive about 700 complaints of suspected foodborne illness each year.[7] All suspected outbreaks of foodborne illness are investigated to determine the number of affected persons, the symptoms of illness, the suspected vehicle, the food source, and the preparation, storage, or handling of food. A reported outbreak of foodborne illness is defined as an incident in which two or more persons have the same disease, have similar symptoms, or excrete the same pathogen after eating a common food or beverage. Poisoning by botulism or by a toxic chemical requires only one ill individual.[8]

Methods

Restaurants

Case restaurants were permanent restaurants with an active food permit in March 1987 and with a reported foodborne outbreak between January 1, 1986 and March 31, 1987. Although 36 restaurants were associated with an outbreak during this period, only 28 were permanent facilities with an active permit and therefore eligible for further analyses. Control restaurants were permanent restaurants with an active food permit in March 1987 and with no reported foodborne outbreak between January 1, 1986 and March 31, 1987. Two controls were randomly selected from eligible controls that had been matched to each case on health

district and routine inspection date (±30 days), yielding 56 control restaurants for analysis.

Data

Data on each outbreak were collected from the Seattle-King County investigation files, including number of affected persons; implicated agent, vehicle, and contributory cause; and laboratory test results. We analyzed two variables from the permit file: type of ownership (corporate versus non-corporate) and seating capacity. All case and control restaurants had known values for at least one of these variables and were included in these analyses. Using the inspection file, we compared the routine inspection that preceded the outbreak for case restaurants with the date-matched inspection for control restaurants. We analyzed overall score, result category, specific violations, classes of violations, and inspection duration. One case and one control restaurant were excluded from the analyses because of incomplete inspection data.

In June 1987, managers of the 28 case and 56 control restaurants were telephoned to collect additional risk factor data. After obtaining informed consent, a trained interviewer questioned the restaurant manager on duty at the time of the call about restaurant characteristics, food preparation practices, employee turnover, training in food sanitation, and attitudes on food poisoning. After exclusions for non-response and interview refusal, 25 case and 48 control restaurants remained for analysis.

Mean scores, t tests, and confidence intervals (CI) were calculated using methods described by Ury.[9] Odds ratios and 95% CI for matched case-control analyses were calculated using PECAN.[10,11] Although we planned to match two control restaurants per case restaurant, exclusions during analysis necessitated a variable matching ratio. When sparse data made odds ratios in the matched analysis indeterminate, but at least one case restaurant and one control restaurant were exposed to a given factor, we calculated unmatched odds ratios and 95% CI.[12] When this was not possible, we applied exact methods to the matched data to calculate the lower 95% CI.[13]

Results

As shown in Table 2, the foodborne outbreaks affected from one to six persons with a mean of 2.9 persons. The implicated pathogen was unknown for most outbreaks; poultry was the most commonly implicated vehicle. The implicated contributory cause for most outbreaks was improper temperature control of food during cooking, cooling, reheating, holding, or storage. The interval between index inspection and outbreak ranged from 2.0 to 14.1 months, with a mean interval of 3.7 months. This interval is less than the four-month inspection interval recommended for all restaurants by the Seattle-King County Public Health Department.[14]

Case restaurants had a significantly lower mean inspec-

tion score (83.8) than control restaurants (90.9) (difference = 7.1, 95% CI = −13.3, −2.18). Restaurants with an overall score of less than 86 were about five times more likely to have an outbreak than those with better scores. Restaurants that received an inspection result of "unsatisfactory" or "suspend permit" were about three times more likely to have an outbreak than those with "satisfactory" results (Table 3). Several specific violations significantly increased the risk of an outbreak, including any improper food protection practice (violations 3–13), especially improper temperature control of potentially hazardous foods (violations 3 and 4), improper storage and handling of equipment (violation 22), and any "critical" violation. Several other individual violations related to improper food protection practices had odds ratios of 2.0 but the confidence intervals included 1.0 (Table 1). Restaurants with inspections lasting longer than 36 minutes, with corporate owners, or with 150 or more seats were also more likely to have outbreaks than restaurants without these characteristics (Table 3). Two factors identified through telephone interviews were positively associated with outbreaks: Chinese cuisine specialty (OR=5.0, 95% CI=1.0, 25.8), and any Asian cuisine specialty (OR=4.0, 95% CI=1.0, 15.6). One factor, American cuisine specialty, had a clearly negative association with outbreaks (OR=0.2, 95% 0.1, 0.7) (Table 3).

Discussion

This study demonstrates that restaurants with poor routine inspection results were at increased risk of foodborne outbreaks. Key risk factors included a low score (less than 86 points), an inspection result warranting follow-up inspection or permit suspension, and violations of recommended food protection measures.

Our study was based on the inspection form used in Seattle-King County which differs from forms used by other locales and the US Food and Drug Administration[15] by assigning greater weight to violations of proper temperature controls of potentially hazardous foods. Most outbreaks in this series were probably caused by improper heating, cooling, cooking, holding, or storage of food—a finding consistent with a nationwide series of outbreaks reported to the Centers for Disease Control.[1] Inspection forms that give less weight to these temperature control factors may be less predictive.

It is widely believed that inspection results vary according to the sanitarian who performs an inspection.[14] We were unable to directly evaluate the quality of inspection data used in this study because Seattle-King County does not routinely require more than one sanitarian to do the same inspection. A recent evaluation in one district of the county where several sanitarians inspected the same restaurant at the same time suggested that the sanitarians were fairly consistent in identifying violations of proper temperature controls and cross-contamination but less consistent on overall score or the combination of violations accounting for that score.*

The strong association between outbreaks and improper storage and handling of equipment (violation 22) is difficult to explain on a biologic basis, and may be spurious because it is based on extremely sparse data. Conceivably, certain equipment violations, such as improper storage or handling of meat slicers, could be hazardous. Alternatively, improper use of equipment may reflect food-handling techniques more directly related to foodborne illness, a consideration if sanitarians do not use standard techniques for identifying violations.

Inspections lasting 37 minutes or more may have been associated with foodborne outbreaks because more time is needed to identify and record multiple violations. Large restaurant size may represent a risk factor simply because such restaurants serve numerous patrons, thus increasing the likelihood of finding two ill persons needed to identify an outbreak. Alternatively, large restaurants may be more likely to have an outbreak because of poor control of food temper-

*Unpublished data, Food Protection Program, Seattle-King County Department of Public Health.

atures, greater food volume, more complex menus, or less closely supervised food handlers. The association of the outbreaks with corporate ownership largely reflects the association of outbreaks with restaurant size. Compared with small noncorporate restaurants, large noncorporate restaurants were more likely (OR=5.0, 95% CI 0.5, 47.1) than small corporate restaurants (OR=2.5, 95% CI 0.6, 10.4) to have an outbreak.

We cannot rule out chance as an explanation for the positive associations with Asian or Chinese restaurants because the lower confidence bounds were 1.0, but these positive associations are plausible because certain food preparation practices in Cantonese-style restaurants have been found to be hazardous.[16] On the other hand, reporting bias could also explain these associations if Seattle-King County residents were more likely to report foodborne illness after eating in Asian restaurants than in other restaurants. Similarly, the apparent "protective" effect of American cuisine specialty could reflect less hazardous food preparation and sanitation practices or less intensive reporting of foodborne illness from American-style restaurants.

Poor inspection results should trigger appropriate education and regulatory action, such as follow-up inspection or permit suspension, which in turn should prevent outbreaks. Because our study illustrates that restaurants with poor inspection results are *more* likely to have outbreaks, it appears that the resulting regulatory action and education were not sufficient to prevent these outbreaks or that the restaurants did not adopt the recommended improvements on a long-term basis. Although we did not directly address this issue in our study, it probably reflects several problems. Restaurants with suspended permits are typically closed for less than 24 hours, a reprimand which might have little impact on a restaurant's profits or reputation. In addition, some restaurant managers complained during the telephone interviews that the education offered by sanitarians at the time of routine inspection is cursory or inconsistent. Finally, sanitarians in Seattle-King County and other locales[17] often report that food sanitation procedures taught at routine inspection have been abandoned by the next inspection.

Although this study demonstrates that the Seattle-King County inspection form can successfully identify restaurants at increased risk of foodborne outbreaks, it also illustrates that more emphasis is needed on regulation and education to prevent outbreaks in restaurants with poor inspection results. Permit suspension and timely follow-up inspections are clearly warranted when low scores or critical violations are noted. Detailed education to food handlers and their supervisors on the risks associated with specific violations is also needed. The risk estimates in Table 1 provide a simple instruction tool: for example, a sanitarian who notes unsafe storage temperatures of potentially hazardous foods (violation 3) could explain that this increases the risk of an outbreak ten-fold. Food protection programs should also assure that sanitarians use appropriate inspection techniques and that food handlers are certified in proper food preparation techniques. Finally, investigation of all complaints of foodborne illness will also help to monitor restaurants that pose an unusual public health risk.

Multiple Program Participation: Comparison of Nutrition and Food Assistance Program Benefits with Food Costs in Boston, Massachusetts

JEAN L. WIECHA, MS, AND RUTH PALOMBO, MS, RD

Abstract: The values of government cash and food assistance benefits are compared to estimated food costs in Boston for households whose sole source of income is Aid to Families with Dependent Children (AFDC) and who have housing in the private sector. Methods developed by the General Accounting Office (GAO) in 1978 are replicated. GAO found that the value of combined benefits can exceed the cost of the United States Department of Agriculture's Thrifty Food Plan. Key assumptions underlying GAO's methodology are challenged, and an alternate method is applied. The new results contradict GAO's conclusions and suggest that Boston food costs exceed the combined value of benefits that AFDC households may receive, although participation in multiple food assistance programs is more beneficial than receipt of benefits from single programs. The authors conclude that food stamps and AFDC benefits indexed to actual costs of living are needed to meet the food needs of low-income families in Boston. (*Am J Public Health* 1989; 79:591–594.)

Introduction

A variety of nutrition and food assistance programs operate in the United States, most of which provide direct benefits to low-income households meeting various eligibility criteria. Frequently, individuals and households eligible for one food assistance program qualify for others as well. Many low-income households also receive Aid to Families with Dependent Children (AFDC), the country's main means-tested cash transfer program. Although food stamp allocations for households are set by the federal government, AFDC benefit levels are set independently by each state. Both are based upon family size, income, and resources.

The use of multiple programs appears to be widespread. The President's Task Force on Domestic Food Assistance estimated that 76 per cent of food stamp households with children ages 5–18 years received free or reduced-price lunches in 1979.[1] Likewise, United States Department of Agriculture (USDA) figures have shown that 62 per cent of children receiving free school lunches are from food stamp households and approximately 42 per cent of food stamp households in the country also receive AFDC.[2] In Massachusetts, about 80 per cent of AFDC recipients receive food stamps.[3]

Some federal analyses have suggested that participation in multiple cash and food assistance programs may provide duplicative benefits to low-income households in excess of their food costs.[1,2,4] For example, in 1978 the General Accounting Office (GAO) published *Federal Domestic Food Assistance Programs: A Time for Assessment and Change*,[4] a report which examined both program administration and effectiveness. In one component, GAO compared the market value of different combinations of cash and food assistance benefits to USDA's Thrifty Food Plan and concluded that ". . . multiple participation . . . has created a situation in which benefits often exceed amounts needed. . . . for thrifty food plan diets."[4] GAO estimated that AFDC households might receive food assistance benefits equal to 230 per cent of the cost of the Thrifty Food Plan.

Other studies have suggested instead that multiple benefits are not excessive.[5–7] For example, the National Evaluation of School Nutrition Programs determined that school meals did not duplicate food stamps in their effect on household resources.[5] MacDonald examined participation in multiple programs using 1979 census information and found that 75 per cent of food stamp recipients and 85 per cent of food stamp eligible nonparticipants remained below the poverty line when the total value of income, cash, and food stamp benefits was considered.[6] In Massachusetts in fiscal year 1987, maximum AFDC and food stamp benefits for a three-person household totaled 83 per cent of federal poverty guidelines.

In this study, we re-examine the issue of participation in multiple programs in metropolitan Boston in the mid-1980s, using analytical methods similar to those presented in the 1978 GAO report.[4] We focus on households in private housing whose sole source of income is AFDC, the group most likely to have "excessive" benefits, according to GAO. In spring 1987, an estimated 10,000 Boston households met this description.[3] Although the GAO procedure is replicated, major assumptions underlying its methodology are challenged, and an alternative method for assessing the adequacy of food benefits is offered.

Methods

GAO Analysis

GAO created seven hypothetical low-income households that varied in size, composition, and ages of household members and determined the cash and food assistance programs for which each household was potentially eligible. One combination of program benefits was analyzed for each type of household and the monthly value of these benefits totaled, based on the reimbursable cost of child nutrition programs, the face value of food stamps, and 30 per cent of the monthly AFDC grant. These totals were compared to the cost of the USDA Thrifty Food Plan for each household. All data were based on program information for Oakland, California in spring 1976. The procedure was replicated for a sample of 95 actual Oakland, California households. GAO described seven of these households in terms of their composition and program participation in its report. Thus, GAO

Ms. Palombo is Director of the Office of Nutrition, MDPH, Boston. This paper, submitted to the Journal February 29, 1988, was revised and accepted for publication September 6, 1988.

© 1989 American Journal of Public Health 0090-0036/89$1.50

provided detailed information on a total of 14 households (seven hypothetical and seven actual).

Massachusetts Sample

The sample consisted of four households chosen from GAO's sample of 14. We excluded 10 of them because they did not receive AFDC (elderly, single males, or intact families) or they participated in a mix of benefit programs identical to one of those assigned to a household in our sample.

The compositions of the GAO households we examined were:

- Three persons: Mother age 29 and daughters ages 10 and 8.
- Four persons: Two households of similar composition:
  1) Mother age 40, sons ages 15 and 4, and daughter age 8.
  2) Mother age 25, daughters ages 7 and 4, and son age 6.
- Five persons: Mother age 32 and daughters ages 12, 10, 4, and 3.

Food Program Benefits—The programs we examined were AFDC, Food Stamps, National School Lunch (free meals), School Breakfast (free meals), and WIC (Special Supplemental Food Program for Women, Infants and Children) for our sample families. For comparable families, GAO examined AFDC, Food Stamps, National School Lunch (free and reduced-price meals), School Breakfast (free and reduced-price meals), Special Milk, and WIC. Because AFDC households would automatically be eligible for free school meals, we did not include reduced-price meals in our analysis. We chose not to include the Special Milk Program because virtually no Boston public schools sponsored it during FY'87 (regulations were still in effect that prohibited sponsorship by public schools that also offered one or more school meals).

Table 1 shows the value of AFDC and selected food assistance benefits for Massachusetts in FY'87. As in the GAO report, value was defined as the cash equivalent (AFDC and food stamps), the actual cost of the benefit (free school breakfast and WIC) to the government, or the actual cost plus the value of donated commodities (free school lunch). AFDC benefits shown are for families in private housing with no other source of income, and designated food stamp allotments are based on the AFDC grants. To determine the potential maximum contribution that food programs can make to food costs, we based our calculations of monthly values on daily participation, as did GAO.

TABLE 1—Value of AFDC and Selected Food Assistance Benefits (Monthly), Spring 1987

Program	Value
AFDC*	$491 (3 persons)
	$571 (4 persons)
	$652 (5 persons)
Food Stamps**	$140 (3 persons)
	$173 (4 persons)
	$200 (5 persons)
Free School Lunch†	$30.75
Free School Breakfast††	$14.75
WIC‡	$32.20

*AFDC: Maximum benefits for families of different sizes are shown, and include an additional $15 per month benefit for private sector housing.
SOURCE: Massachusetts Department of Public Welfare.

**Food stamps: Allotments were calculated for households of different sizes receiving maximum AFDC payments. The standard deduction of $99 and the maximum shelter deduction of $149 were subtracted to obtain net income on which the food stamps allotment was based.
SOURCE: Massachusetts Department of Public Welfare.

†Free school lunch: The federal reimbursement rate of 142.5¢ per meal plus 11.25¢ in commodities was multiplied by 20 school days per month for an estimated value of $30.75 per month.
SOURCE: Massachusetts Department of Education.

††School breakfast: The average federal reimbursement rate of 73.75¢ per meal was multiplied by 20 school days per month for an estimated value of $14.75 per month (rounded to $14.80).

SOURCE: Massachusetts Department of Public Health.

While GAO considered one program participation mix for each of its households, we assigned several to each household in our sample.

Food Costs—Food costs were estimated in two ways, referred to as the Thrifty Food Plan (TFP) used by GAO, and the Estimated Household Food Costs devised by us. We estimated food costs in Boston indirectly, using data from the Bureau of Labor Statistics and the USDA. The cost of food purchased for home consumption in the Boston area, last measured in October 1981, was updated for use in this study.[8] The "intermediate" budget which most closely approximated average food costs[9] was updated by 19.1 per cent, the per cent change between the fall of 1981 and May 1987 in the Consumer Price Index for food at home in the Boston Metropolitan area (average cost changes for a food basket of cereals, produce, meat, and dairy products at selected stores).

The estimated monthly cost of food at home was $498.70 for the Bureau of Labor Statistics' prototypical family (mother, age 35; father, age 38; and two children, one under age 6 and the other between ages 6 and 15). To estimate monthly food costs for households of different compositions, the cost of the Thrifty Food Plan for each member of the family (taken from USDA data) was summed and the per cent of the total cost attributable to each member of the family was calculated. Results as a per cent of total household monthly food costs were: father, 29.9 per cent; mother, 27.1 per cent; older child 25.9 per cent; and younger child, 17.1 per cent. Multiplying these percentages by the May 1987 food at home cost estimate ($498.70) gave per capita results. On the basis of age distributions consistent with Thrifty Food Plan terminology, these figures were: father, age 20–50, $149.60; mother, age 20–50, $135.10; child through age 5, $85.30, and child age 6 through 16, $129.20 (figures rounded to nearest $0.10).

Results

We compared cash and food assistance benefits to food costs replicating the GAO analysis. Maximum monthly food assistance benefits (Table 1) were combined with 30 per cent of AFDC and compared to Thrifty Food Plan Costs (Table 2). Using the alternative approach, we compared maximum monthly food assistance benefits, excluding any contribution from AFDC, to Estimated Household Food Costs. Results are shown in Table 3. The results of the two types of analysis are compared in Table 4.

By the original GAO estimates, benefits for these households were as high as 203 per cent of Thrifty Food Plan Costs (Table 4, column 1). Using GAO's methodology and Boston data for FY'87, we found the value of government benefits included in the study provided 134.7 per cent to 194.5 per cent of the cost of the Thrifty Food Plan (Table 4, column 2). However, using the alternative approach (excluding AFDC and comparing the values of food assistance benefits to

	AFDC(5) + FS(5) + SL(2) + SB(2) + WIC(2)	551.00	$297.80	185.0

*Abbreviations are: FS, food stamps; SL, free school lunch; SB, free school breakfast; and WIC, Special Supplemental Food Program for Women, Infants, and Children.

**Monetary values of benefits were derived from the values in Table 2.

†Monthly household food costs were estimated by using monthly per capita costs derived under "Methodology." These were: Mother age 20–50, $135.10; child through age five, $85.30; and child six through fifteen, $129.20. Thrifty Food Plan costs are from USDA, February, 1987.

††Mother age 40, sons ages 15 and 4, and daughter age 8

‡Mother age 25, daughters ages 7 and 4, and son age 6.

estimated household food costs in Boston), the data suggest that food stamps, school meals, and WIC are able to meet only 33.8 per cent to 66.3 per cent of estimated food costs (Table 4, column 3).

Discussion

The main differences between GAO methods and the new method derive from two assumptions. First, the GAO assumed that AFDC households would use 30 per cent of their grant for food. However, the Massachusetts Department of Public Welfare has shown that 63 per cent of AFDC recipients spend more than 75 per cent of their grant on rent.[10] Moreover, although the actual rents paid by AFDC households are not available, costs for private, unsubsidized rental units in Boston suggest that AFDC grant levels would not allow 30 per cent to be available for food. A Spring 1987 industry survey found that average monthly rents within Boston were $715 for a one-bedroom apartment (neighborhood averages ranged from $272 to $893) and $944 for a two-bedroom apartment (neighborhood averages $529 to $1260).[11] There were no vacancies in many of the less expensive neighborhoods. In contrast to these rents, Massachusetts AFDC benefits for three-, four-, and five-person households in Spring 1987 were $491, $571, and $652 per month, respectively (Table 1). AFDC benefits in Massachusetts rose 50 per cent from 1970 to 1985, whereas median Boston rents increased 329 per cent in the same period.[10]

Second, the GAO assumed that Thrifty Food Plan costs as given were an appropriate standard for measuring the adequacy of benefits. However, actual Thrifty Food Plan costs in Boston are below estimated food costs for all

TABLE 3—Comparison of Value of Selected Food Assistance Benefit Mixes to Estimated Household Food Costs

*Current study shows a range because several program mixes were analyzed for each household. GAO analyzed one mix per household.

households shown in Tables 2 and 3. This finding is in keeping with data from the 1977–78 Nationwide Food Consumption Survey which indicated that 69 per cent of low-income households surveyed spent 110 per cent or more of their potential food stamp allotments on food.[12] A recent study by the Project Bread Food Stamp Hotline also found that food costs in Boston greatly exceed estimated Thrifty Food Plan costs.*

Thus we believe that GAO may have overstated the ability of government cash and food assistance benefits to meet actual food costs. Even though it is more beneficial for a family to take advantage of multiple nutrition and food assistance programs, maximum benefits from all these programs may not enable the most needy families in the Boston area to purchase an adequate supply of food. We conclude that food stamps and welfare benefits that are indexed to actual costs of living are needed if low-income families in the Boston area are to meet their food costs.

Community-Based Nursing Administration: New Graduate Program at Penn

The University of Pennsylvania School of Nursing is developing a master's level educational program to prepare nurse managers for positions in community-based health care agencies. The effort is funded by a $160,000 grant from the W. K. Kellogg Foundation of Battle Creek, Michigan, and is managed by Cynthia Scalzi, PhD, RN, director of Penn's Nursing Administration Program.

The program will be designed with the assistance of a task force comprised of faculty and community leaders who will provide a broad base of community support for the program and assist in the development of a needs assessment survey.

The School of Nursing recognizes that nurse administrators today need superior planning and administrative expertise to handle the legal, regulatory, marketing, quality assurance, and financial issues that are unique to community-based health care programs.

Fatal Violence among Spouses in the United States, 1976–85

JAMES A. MERCY, PHD, AND LINDA E. SALTZMAN, PHD

Abstract: In this paper we examine patterns and trends in homicides between marriage partners in the United States for 1976 through 1985 using data from the Federal Bureau of Investigation's Supplemental Homicide Reports (FBI-SHR). We identified 16,595 spouse homicides accounting for 8.8 per cent of all homicides reported to the FBI-SHR during this 10-year period. The rate of spouse homicide for this 10-year period was 1.6 per 100,000 married persons. The risk of being killed by one's spouse was 1.3 times greater for wives than for husbands. Black husbands were at greater risk of spouse homicide victimization than Black wives or White spouses of either sex. The risk of victimization was greater for spouses in interracial than in intraracial marriages and increased as age differences between spouses increased. From 1976 through 1985, the risk of spouse homicide declined by more than 45.0 per cent for both Black husbands and wives but remained relatively stable for White husbands and wives. Demographic patterns in the risk of spouse homicide were similar to those reported for nonfatal spouse abuse suggesting that the causes of spouse homicide and nonfatal spouse abuse may be similar. (*Am J Public Health* 1989; 79:595–599.)

Introduction

Intentional physical violence between spouses is a long-standing social problem not seriously addressed by researchers or policy-makers in the United States until the 1970s. The pervasiveness of violent events in marital relationships has since been convincingly documented.[1–4] Relative to the prevalence of abusive behavior between spouses, however, little attention has been given to the physical injuries associated with such behaviors, and there has been no attempt to undertake a population-based study of spouse homicide. To help address this gap in our understanding of the public health implications of spouse abuse, we undertook an investigation of spouse homicides in the United States for the years 1976 through 1985 to determine the demographic patterns for the risk of being murdered by one's spouse, and document annual trends in the rate of spouse homicide.

Methods

We obtained homicide data from the Federal Bureau of Investigation (FBI) for the years 1976 through 1985. On a monthly basis, state and local law enforcement agencies voluntarily report homicides and other major crimes to the FBI through the Uniform Crime Reporting Program (UCR).[5] The term homicide refers to those offenses reported to the FBI as murder and non-negligent manslaughter, i.e., "the willful (non-negligent) killing of one human being by another."[7] The classification of this offense is based solely on police investigation as opposed to the determination of a court, medical examiner, coroner, jury, or other judicial body. This study focuses on homicides in which the relationship of the victim to the offender was determined through police investigation as that of a legal or common-law husband or wife. We further focused on those homicides that police investigations categorized as being criminal (i.e., unjustifiable) and having only one offender.

Supplemental Homicide Reports (SHR) accompany UCR (Uniform Crime Reporting) reports on murder and non-negligent manslaughter include information on the sex, age, and race of victims and offenders, the victim-to-offender relationship, the circumstances under which the homicide occurred, and the geographic location of the homicide. We analyzed data by race only for Blacks and Whites because the low frequency of spouse homicide among other races makes it difficult to identify meaningful patterns.

Population estimates used to compute homicide rates were obtained from published data prepared by the Bureau of the Census.[8–15] Estimates of the "now married" population include only persons ages 15 years and older who were married for the first time, remarried, separated, or in common-law marriages. Therefore, this analysis was limited to homicides in which the victim was age 15 or older. Age-adjusted spouse homicide rates were calculated by the direct method of standardization,[16] with the 1980 United States "now married" population as the standard.

Population estimates used to calculate homicide rates for interracial and intraracial marriages, and by spouse-age differences, were only available from the 1980 census.[17] For categories of these variables, homicide rates were calculated by dividing the average frequency of homicide for the three-year period 1979 through 1981 by 1980 population estimates.

Results

In the United States from 1976 through 1985, 16,595 homicides involved persons killed by their spouse in the context of a single-offender criminal homicide (Table 1). The 16,595 spouse homicides exclude 340 single-offender homicides that involved an offender and victim who were divorced from each other, 193 homicides with multiple offenders, and 113 homicides that were classified as justifiable. These 16,595 victims constituted 8.8 per cent of all reported homicide victims in the United States during this 10-year period. In 98.6 per cent of these incidents, there was only one victim.

Sex, Race, and Age Patterns

The spouse homicide rate for this 10-year period was 1.6 per 100,000 married persons, with wives being at 1.3 times the risk of husbands (Table 2). Blacks accounted for 45.4 per cent of all spouse homicide victims. The rate of spouse homicide among Blacks was 8.4 times higher than that for Whites. White wives were at almost twice the risk of being killed by a spouse as White husbands, whereas Black wives had victim rates that were moderately lower than those for Black husbands. Age-adjustment of these rates left them virtually unchanged.

Mercy, PhD, Intentional Injury Section, Epidemiology Branch, Division of Injury Epidemiology and Control, Center for Environmental Health and Injury Control, Centers for Disease Control, Atlanta, GA 30333. Dr. Saltzman is also with the Division of Injury Epidemiology and Control, CEHIC, CDC. This paper, submitted to the Journal February 11, 1988, was revised and accepted for publication September 8, 1988.

TABLE 1—Number and Per Cent of Husband and Wife Victims by Category of Homicide, United States, 1976–85

Category of Homicide	Husbands		Wives		Total	
	Number	Per Cent	Number	Per Cent	Number	Per Cent
Spouse Homicides						
Single Victim/Single Offender	7,105	43.4	9,262	56.6	16,367	100.0
Multiple Victim/Single Offender	10	4.4	218	95.6	228	100.0
Total	7,115	42.9	9,480	57.1	16,595	100.0
Ex-Spouse Homicides*						
Single Victim/Single Offender	131	40.1	195	59.8	326	100.0
Multiple Victim/Single Offender	0	0.0	14	100.0	14	100.0
Total	131	38.5	209	61.5	340	100.0
Other Spouse-Related Homicides*						
Multiple Offender†	147	76.2	46	23.8	193	100.0
Justifiable	107	94.7	6	5.3	113	100.0
Total	254	83.0	52	17.0	306	100.0

*These categories of homicide have been excluded from subsequent analyses in this study.

†Includes three spouse homicides in which there were multiple victims.

Age-specific rates for Black husbands and wives exhibited a strong inverse association with age (Figure 1). Victim rates for Black wives and husbands peaked at 14.0 in the 15- to 24-year age category and then declined with age. Among Whites, however, age-specific spouse homicide rates did not decline consistently with age. Overall, racial differences in spouse homicide rates declined with age.

Spouse Differences in Race and Age

Of spouse homicides occurring from 1979 to 1981, 96.3 per cent occurred in intraracial marriages. Spouse homicides in marriages where the husband was Black and the wife was White constituted 1.4 per cent of the total, and marriages where the husband was White and the wife was Black accounted for 0.5 per cent. Spouse homicide incidence rates were 7.7 times higher in interracial marriages relative to intraracial marriages. The patterns in this risk varied by race and sex. White husbands, White wives, and Black wives were at greater risk of being killed by a spouse in an interracial than an intraracial marriage, whereas Black husbands were at less risk (Table 3).

The risk of spouse homicide victimization for both husbands and wives increased as the age difference between husbands and wives increased. Among couples where the husband was two or more years younger than the wife, the spouse homicide rate was 5.0 per 100,000 compared with 2.6 among couples whose ages were within 1 year of each other and 3.6 among those couples where the wife was two or more years younger than the husband. This positive association between the risk of spouse homicide victimization and spouse age differences held for husbands and wives of both races

TABLE 2—Spouse-Victim Homicide Rates* by Race of Victim for Husbands and Wives, United States, 1976–85

Race	Husbands	Wives	Total
White	0.7	1.3	1.0
Black	9.7	7.1	8.4
Total	1.4	1.8	1.6

*Rates are per 100,000 married persons.

Note: Excluded are 26 homicides for which information on race of victim was missing and 270 homicides occurring among victims of races other than White or Black.

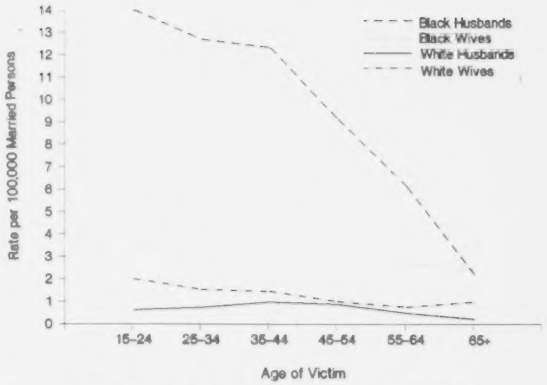

FIGURE 1—Spouse-Victim Homicide Rates by Race and Age for Husbands and Wives, United States, 1976–85

(Figure 2). This association also held regardless of the victim's or offender's age at the time of the homicide.

Weapon Involvement and Circumstantial Characteristics

Firearms were used in the perpetration of 71.5 per cent of spouse homicides from 1976 to 1986. Wife and husband victims were almost equally likely to have been killed by a firearm (71.0 per cent versus 72.2 per cent). Husband victims, however, were more likely to have been killed by a cutting instrument than wife victims (24.7 per cent versus 12.1 per cent), whereas wife victims were more likely to have been bludgeoned to death (11.8 per cent versus 1.6 per cent). White spouses were more likely to have been killed with a firearm than Black spouses. Among White victims, 83.2 per cent of the husbands and 72.5 per cent of the wives were killed with a firearm as compared to 63.9 per cent of Black husbands and 69.4 per cent of Black wives.

Arguments were noted as the circumstance most immediately associated with the killing in 67.2 per cent of spouse homicides. Arguments were more likely to be associated with the killing of husbands than wives (76.0 per cent versus 60.7 per cent) and the killing of Black spouses compared with White spouses (76.7 per cent versus 59.8 per cent).

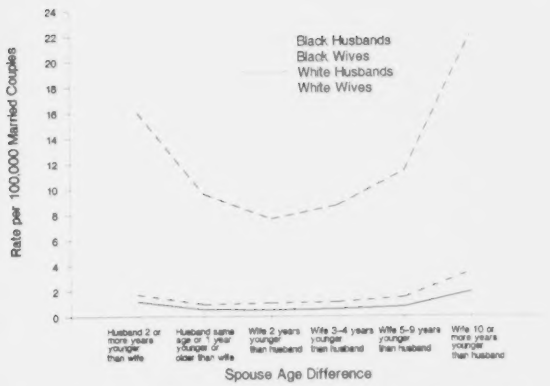
TABLE 3—Rate† and Number* of Spouse-Victim Homicide by Racial Composition of Marriage for Husbands and Wives, United States, 1980

Race/Sex of Victim	Racial Composition of Marriage		Risk Ratio
	Interracial	Intraracial	
Husbands			
White	17.1 (14)	0.8 (1,002)	21.4
Black	8.9 (25)	12.2 (1,252)	0.7
Wives			
White	17.4 (49)	1.4 (1,784)	12.4
Black	13.4 (11)	9.6 (985)	1.4

*The number of homicides reported in parentheses under each homicide rate represents the frequency of homicides for a three-year period (1979–81). To calculate rates for this table the average annual frequency for the three-year period was divided by population estimates for 1980.

†Rates are per 100,000 married couples.

Note: Excluded are 10 homicides for which information on race of victim was missing and 74 homicides occurring among victims of races other than White or Black.



Black Husbands
Black Wives
White Husbands
White Wives
Rate per 100,000 Married Couples
Husband 2 or more years younger than wife
Husband same age or 1 year younger or older than wife
Wife 2 years younger than husband
Wife 3–4 years younger than husband
Wife 5–9 years younger than husband
Wife 10 or more years younger than husband
Spouse Age Difference

FIGURE 2—Spouse-Victim Homicide Rates by Spouse Age Differences and Race for Husbands and Wives, United States, 1980

Yearly Trends

Between 1976 and 1985, the spouse homicide rate dropped by 31.6 per cent from 1.9 per 100,000 married persons in 1976 to 1.3 in 1985. This decline in victimization rates was more dramatic for husbands than wives. The spouse homicide rate for husbands declined by 43.5 per cent; the rate for wives declined by 17.0 per cent.

When spouse homicide rates are further broken down by race, it becomes evident that the decline noted in the overall rate is almost entirely attributable to declines in the rates for Black husbands and wives. From 1976 to 1985, the spouse homicide rate for Black husbands declined by 52.0 per cent from 12.7 to 6.1, and the rate for Black wives declined by 45.8 per cent from 9.6 to 5.2 (Figure 3). In contrast, the rate for White husbands did not exhibit a consistent time trend, although from the beginning to the end of this 10-year period it declined from 0.7 to 0.5 per 100,000. The rate for White wives increased negligibly from 1.2 to 1.3 per 100,000. The risk of spouse homicide victimization for Black husbands relative to White husbands declined from 18.1 in 1976 to 12.2 in 1985. Similarly, the risk for Black wives relative to White wives declined from 8.0 in 1976 to 4.0 in 1985. Age-adjustment of these rates left the annual trends virtually unchanged.

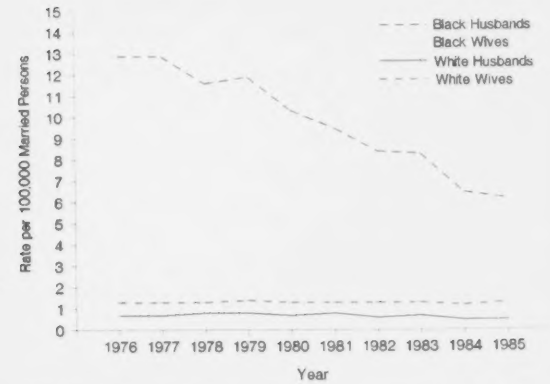


FIGURE 3—Spouse-Victim Homicide Rates by Race for Husbands and Wives, United States, 1976–85

Discussion

The finding that husbands and wives were nearly equal in the risk of spouse homicide victimization is also apparent in some studies of nonfatal spouse abuse. In both the 1976 and 1985 national family violence surveys, husbands and wives were at very similar risks of being physically abused by their spouses.[1,2] Other studies have reported similar findings.[4,18–21] Studies relying on police statistics, however, generally report that in most cases of nonfatal spouse abuse known to police the victims are women.[22–24]

Violent behavior by wives directed at their husbands may reflect acts of self-defense or retribution. Studies of homicides between intimates show that they are often preceded by a history of physical abuse directed at the women[25,26] and several studies have documented that a high proportion of women imprisoned for killing a husband had been physically abused by their spouses.[27,28] In a study comparing battered women who had killed their partners with abused women who had not killed their partners, Browne[29] found that the frequency and severity of wife abuse was associated with homicide. The weight of available evidence suggests that often wives kill their husbands in the context of a history of wife abuse.

Blacks had substantially higher spouse homicide rates and different patterns of risk than Whites. The risk of nonfatal husband and wife abuse has also been reported to be higher among Blacks than Whites.[1,30] Racial differences in the risk of spouse homicide, however, may only be a reflection of socioeconomic factors. Previous homicide research has demonstrated that socioeconomic factors are more important than race in explaining variations in homicide rates across aggregate units of analysis (e.g., states and cities).[31–33] Furthermore, other research indicates that variations in homicide rates among family and acquaintances may be more sensitive to socioeconomic factors than homicide rates among strangers.[34,35]

The strong inverse association found between age and the risk of spouse homicide for Black husbands and wives, but not for White husbands and wives, is a new finding. Research on nonfatal spouse abuse has also indicated an inverse association between age and risk,[1] but this finding has not been broken down by race. These patterns within Black marriages may reflect the well established association between violence and youth found in our society.[1] In addition, violent marriages may be more likely to dissolve through divorce, separation, or death than nonviolent marriages, thus reducing the chances that they would be as prevalent among older as younger couples.[1]

Differences between the race and age of spouses were found to be associated with a higher risk of homicide victimization. Although the risk of nonfatal spouse abuse has not been examined by differences in race or age, spouses in mixed religion marriages and wives in marriages where their educational or occupational level is high relative to their husband have been found to be at greater risk of physical abuse than spouses and wives in marriages without such differences.[1,20,36,37] It may be that persons with different racial or generational backgrounds bring very different outlooks and lifestyles to a marriage that may contribute to more conflict, greater stress, and, ultimately to violence. External pressures brought on by family ostracism or by people

outside the marriage, particularly for those partners in interracial marriages, could also contribute to stress and violence within the marriage.[1]

Firearms were used in the commission of most spouse homicides. In fact, firearms were more likely to be used in spouse homicides than nonspouse homicides (71.5 per cent versus 60.5 per cent). The presence of a firearm in the home may be a key contributor to the escalation of nonfatal spouse abuse to homicide.[38]

The risk of spouse homicide victimization declined between 1976 and 1985. This decline is almost entirely attributable to declines in the risk faced by Black spouses. Rates of severe nonfatal wife and husband abuse have been reported to have declined by 21.1 per cent and 4.3 per cent, respectively (Table 4).[2] These trends are in the same direction as those we found for spouse homicide. The decline in the risk of spouse abuse may be attributable to the spread of treatment programs and battered woman's shelters, the greater acceptability of divorce and changes in the structure of families (e.g., increases in age at first marriage), or to economic changes which may have decreased levels of stress on families.[2] These explanations, however, beg the question of why the decline in spouse homicide rates was limited to Black husbands and wives.

There are a number of actual and potential biases affecting both the number of spouse homicides and the estimates of the married population that should be considered when interpreting the results of this study. First, from 1976 through 1985 between 2 per cent and 4 per cent of the United States population was not served by law enforcement agencies participating in the FBI's Uniform Crime Reporting (UCR) Program.[5] In addition, approximately 4 per cent of the homicides reported to the FBI through the UCR were not accompanied by a Supplemental Homicide Report (SHR) form, which contains the information used in compiling the computer file used in this analysis. A second potential source of bias results from the FBI's monthly reporting requirement. For homicides occurring immediately before the FBI reporting deadline, the offender-to-victim relationship may be unknown at the time a report is made. It is possible, therefore, that some spouse homicides are hidden in the "undetermined relationship" category. A third potential source of bias is law enforcement use of inconsistent or vague criteria in identifying common-law marriages. There is no FBI reporting provision to apply a uniform definition for common-law status.

There are at least two potential biases in estimates of the population of married persons used in this study to calculate rates. Studies matching marital status as classified on death certificates with census records have found a tendency for widowed and divorced persons, especially between ages 15 and 44 years, to report their marital status to the census as married or single.[39–41] Meaningful differences in the self-reporting of martial status by race were not evident. Because of the large number of married persons between the ages of 15 and 44 years relative to the number of widowed and divorced persons, the effect of this bias on estimates of the population of married persons was judged to be negligible.[39] One other potential bias in estimates of the population of married persons concerns the ascertainment of common-law marriages in the census. Since the census relies on self-reports for information on marital status, respondents may define themselves as not married (i.e., single, divorced, or widowed), even though they may be in a relationship which is legally considered a common-law marriage.

Comparisons of data from studies of nonfatal spouse abuse to spouse homicide data presented here show a substantial degree of congruence between the demographic groups at high risk. Also, rates of both nonfatal and fatal spouse abuse show similar declines in the level of risk. These findings are consistent with the possibility that nonfatal spouse abuse and spouse homicide have a common etiology and that spouse abuse may escalate from less severe forms of physical abuse to forms that have a greater likelihood of causing injury or death. Thus, incidents of nonfatal spouse abuse and spouse homicide may be more appropriately viewed in the context of a series of violent events rather than as isolated events.[42] Repeated exposure to violence is likely to bring victims into repeated contact with a broad range of health and social services. Thus, contacts of abuse victims with emergency rooms, law enforcement agencies, social services, and physicians may provide a critical opportunity to prevent further injury or even death.

TABLE 4—Comparison of Changes in Spouse Homicide Rates* with Changes in an Index of Marital Violence between 1975 and 1985, United States

Violence Index	Year		Percent Difference
	1975/1976†	1985	
Spouse Homicide			
Wife Victim	2.00	1.70	−17.0
Husband Victim	1.70	.96	−43.5
Severe Violence			
Wife Victim	3800	3000	−21.1
Husband Victim	4600	4400	−4.3

*Rates for spouse homicide are expressed per 100,000 husbands or wives while rates for severe violence are expressed per 100,000 couples. SOURCE: Straus MA, Gelles RJ.[2] This index represent rates of nonfatal violent behaviors (i.e., kicking, biting, punching; hitting or attempting to hit with an object; beating; threatening with a knife or gun; or using a knife or gun).

†The spouse homicide rates reported in this table pertain to the year 1976, but the rates for the index of severe violence pertain to 1975.

ACKNOWLEDGMENTS

We thank Mark L. Rosenberg, Richard J. Waxweiler, Amy Levenson, Bill Rokaw, and Diane Roberts for their contributions to this paper. We also acknowledge the cooperation of Murray Straus in providing us with data on nonfatal spouse abuse. Finally, we thank the staff of the Uniform Crime Reporting Program at the Federal Bureau of Investigation for providing us with these data and answering our questions concerning their origin and use. This study was presented at the Third National Family Violence Research Conference, July 6–9, 1987, Durham, NH.

May Conference on "Meaning of the Holocaust for Bioethics"

The Center for Biomedical Ethics at the University of Minnesota will sponsor a conference on the "Meaning of the Holocaust for Bioethics," May 17–19, 1989, at the Radisson University Hotel in Minneapolis. Major themes include medical experimentation in the Third Reich, eugenics and euthanasia, the evolution of Nazi biomedical policies, the ethical status of Nazi research results, and analogies from the Nazi era in contemporary ethical debates.

Speakers include: Arthur L. Caplan (Director of the Center for Biomedical Ethics at the University of Minnesota), Jay Katz (Yale University), George Annas (Boston University), Robert Pozos (University of Washington), Benno Muller-Hill (University of Cologne), Peter Rossel (University of Copenhagen), Ivanyushkin Ye (Soviet Academy of Sciences), Ruth Macklin (Albert Einstein College of Medicine), and William Seidelman (McMaster University).

For further information, contact Continuing Medical Education, Box 202 UMHC, 420 Delaware Street SE, Minneapolis, MN 55455; telephone (612) 626-5525.

The Effect of Occupational, Marital and Parental Roles on Mortality: The Alameda County Study

PAMELA KOTLER, PHD, AND DEBORAH LEE WINGARD, PHD

Abstract: This study investigated the impact of combining marital, parental, and occupational roles upon 18-year risk of mortality from all causes. The respondents were 3,700 participants in the Human Population Laboratory cohort ages 35–64 who completed a comprehensive health and psychosocial questionnaire in 1965 and were followed for mortality status through 1982. Employment status and type of employment were not found to predict mortality risk among women. Contrary to the multiple roles hypothesis, there was virtually no impact upon mortality of increasing numbers of children among employed women, except possibly among single working parents. The major impact of children was felt by housewives who had significantly elevated risks when a child was present in the home or when they had four or more children. Neither the number of children nor the presence of a child in the home affected mortality risk of men. Controlling for a variety of factors thought to be related to mortality in a logistic regression analysis did not change the foregoing relation. (*Am J Public Health* 1989; 79:607–612.)

Introduction

Vital statistics show that women live longer than men.[1–4] One explanation proffered is that fewer women are employed outside the home, perhaps protecting them from risk factors of work. The last 30 years have seen a tremendous increase in women entering and remaining in the labor force: in 1950, 33 per cent of American women were employed; in 1985, the proportion had risen to 64 per cent.[5] The increase has been most dramatic among women with young children. Nevertheless, most cross-sectional[6–8] and prospective[9,*] studies show few differences in health between housewives and working women. Where differences exist, they tend to favor working women.[10–14]

Because most women continue to retain major responsibility for child care and homemaking when employed outside the home, it has been suggested that role overload and role conflict may adversely affect women's health.[2,15] Although employed mothers do experience increased stress and role conflict,[13,16,17] only one study has documented any prospective relation between multiple role responsibilities and morbidity.[18] In the Framingham Study, Haynes and Feinleib[18] found that while employed women and housewives did not differ in their risk of coronary heart disease, the risk of heart disease rose with the number of children among working women but not among housewives. Specifically, the excess risk of coronary heart disease was concentrated among ever-married clerical workers with children, particularly those married to blue-collar workers; this relation was not explained by standard coronary risk factors. Haynes and Feinleib theorized that the demands of paid employment and rearing a family may be excessive for some women. Verbrugge[19] also found that clerical workers in Detroit tended to have more symptoms and chronic health problems, and to use more prescription drugs than other groups of employed women.

An alternative view is that active involvement in the labor force may improve women's health, since employment can offer intellectual stimulation, productive activity, more social contacts and support, and greater income. These gratifications may outweigh stress arising from role overload or role conflict, particularly for women who are working by choice and not by necessity. Studies using data from the National Health Interview Survey tend to support this view; employed women with children were the healthiest group of women on a number of measures of morbidity, while women with few or no roles were among the least healthy.[19–21] These studies cannot discount the healthy worker effect—women who are in poor health tend to leave or never enter the labor force, leaving only the healthiest women in the labor force.

Although the issue of multiple role responsibilities has generally been treated as a women's issue, many men are involved in child care and household management and also have more responsibility as the size of the family increases. Another study of the Framingham data[22] found that men with three or more children had a risk of developing coronary heart disease 2.3 times that of men with no children. This effect remained after controlling for standard risk factors.

The current study examined the effect of multiple role responsibilities on the risk of mortality from all causes over an 18-year period among both men and women in Alameda County, California.

Methods

Study Population

In 1965, the Human Population Laboratory of the California State Department of Health Services surveyed a probability sample of Alameda County residents.[23,24] An extensive questionnaire, returned by 86 per cent of those contacted, included information on physical health status, health behaviors, employment status, family responsibilities, social contacts, and satisfaction with life. The present sample is restricted to the 1,731 men and 1,969 women who were between 35 and 64 years of age in 1965.

Mortality data were collected for the 18-year period 1965–82 for 97 per cent of the respondents.[23] A computer linkage was established with the California Death Registry and respondents were identified who died within the State of California. For those people who were not located and who had not died within the state, out-of-state death certificates

were sought from the state of birth. Through this process, 545 people were identified as having died during the interval 1965–82.

Women were categorized as working women (n = 726) if they had been employed outside the home fulltime for at least 50 per cent of their adult lives over the age of 22. Women were designated as housewives (n = 731) if they did not have the necessary years of work experience and if, in 1965, they indicated that they were housewives. The modal category of years worked at a fulltime job was 16–20 for the working women and never for the housewives. This strategy left 512 women who did not have the necessary years of work experience, but in 1965 were working fulltime or otherwise did not consider themselves to be housewives. These women were excluded from the analysis. All men ages 35–64 (n = 1,731) were included in the sample on the assumption that most men have been employed fulltime at least 50 per cent of their adult lives.

Variables

Type of occupation was coded into three major categories using the Dictionary of Occupational Titles: white collar workers (professionals, semi-professionals, technical workers, proprietors, managers, and officials); clerical and sales workers; and blue collar workers (foremen and craftsmen, operatives, apprentice craftsmen, service workers, laborers and private household help).[25] Type of occupation was not asked of women who said they were housewives in 1965, so only 567 of the working women responded to this question.

Marital status was categorized as single, married, or widowed/divorced/separated. Parenthood was assessed both as total number of children, and the presence or absence of a child between the ages of 3 and 19 in the home in 1965.

In addition to variables concerning role statuses, 12 variables considered risk factors in mortality studies were analyzed. These included four sociodemographic variables, two physical health variables, three health behaviors which have been established as independent risk factors, and three psychosocial variables. The categorization of these variables is presented in the Appendix.

Statistical Analysis

Age-adjusted relative risks of mortality and the Mantel-Haenszel chi-square statistic[26] were computed. The multiple logistic regression model[27] was used to estimate individual and joint effects of predictor variables on the risk of mortality simultaneously.

Results—

The sample studied consisted of 3,188 people ages 35–64 in 1965, 1,731 men and 1,457 women, of whom 726 were working women and 731 were housewives. Of the working women, 513 were employed in 1965 and 213 were not. As can be seen in Table 1, working women were far more likely than men to be clerical and sales workers and less likely to be white or blue collar workers. Fewer working women than men or housewives were married, had any children, or a child living in their home.

Age was the only sociodemographic characteristic on which working women and housewives did not differ. Working women had higher education, were more likely to be Black, and to have higher household incomes. When compared to men, working women were more likely to have completed high school. Men and working women had similar distributions of age, race, and income. Health behaviors, physical health status, and psychosocial characteristics were very similar for working women and housewives. However, working women were more likely to be current smokers and to drink alcohol (of any amount). Compared to working women or housewives, men were much more likely to drink alcohol, smoke cigarettes, and be physically active, and less likely to visit the physician and report poor physical health status.

TABLE 1—Prevalence* of Occupational, Marital, and Parental Roles among Men, Working Women, and Housewives in the Alameda County Cohort Ages 35–64 Years in 1965**

Role	Men		Working Women		Housewives	
	N	Per Cent	N	Per Cent	N	Per Cent
Occupation***						
White collar	584	33.8	152	26.8	...	...
Clerical, sales	202	11.7	240	42.3	...	...
Blue collar	938	54.4	175	30.9	...	...

No	696	42.0	359	54.0	278	38.2

*Prevalence = per cent distribution

**For all variables the distribution in men and housewives was significantly different from that in working women ($p < 0.001$) based on chi-square statistic.

***Working women (limited to 567 women answering this question).

Mortality varied by gender during the period from 1965 to 1982; 342 men and 203 women died. Age-adjusted 18-year risks of mortality from all causes showed that men had a higher risk of mortality than women; 19.8 per cent for men and 13.6 per cent for all women (RR = 1.5, CI = 1.2, 1.7). Among the women, housewives had a mortality risk of 14.2 per cent and all working women a risk of 13.5 per cent (RR = 1.05, CI = 0.8, 1.4). When housewives were compared to the 513 women who were currently employed in 1965, the relative risk was 1.2 (CI = 0.9, 1.7). As expected, mortality risks among both men and working women who were not employed in 1965 were substantially higher than the employed (RR = 2.4, CI = 1.9, 3.1 for men and RR = 1.7, CI = 1.1, 2.4 for women).

Figure 1 presents age-adjusted 18-year risks of mortality among men and women according to the type of work usually performed. Among working women, there were no substantial differences in mortality risk by type of work, nor did any of these groups differ from housewives. Among men, blue collar workers had the highest risk, but this was not substantially different from the risk of white collar workers (RR = 1.2, CI = 0.9, 1.4) or clerical and sales workers (RR = 1.2, CI = 0.8, 1.6). Among each of the three occupational groups, men had higher risks of mortality than did women, especially among blue collar workers (RR = 1.4, CI = 1.0, 2.0).

Adjustment for the effects of parenthood and the 12 variables shown in the Appendix had little impact on the pattern of mortality seen in Figure 1. The estimated relative risk for men compared to women was 1.7 (CI = 1.3, 2.1) after adjustment. The relative risk for working women compared to housewives was 1.04 (CI = 0.7, 1.5) after adjustment. We

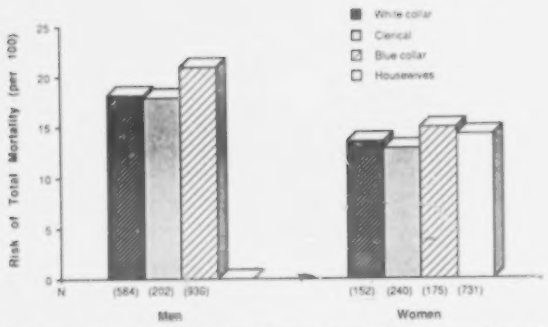

FIGURE 1—Age-Adjusted 18-Year Risk of All-Cause Mortality among Men and Women* by Type of Work
***with information available on type of work.**

examined the influence of each variable on mortality separately for men, housewives, and working women. Marital status was related to mortality risk in this study, especially for men (Table 2). Among all three groups, married people had the lowest risk; single people had intermediate risk, and widowed, divorced or separated people had the highest rates. (There were only four single housewives).

As seen in Table 2, number of children had no impact upon age-adjusted mortality risk for the men or working women. However, housewives with four or more children had a risk of mortality that was almost twice as high as that of housewives with fewer than four children (RR = 1.8, CI = 1.2, 2.5). Mortality risks did not differ by presence or absence of a child between the ages of 3 and 19 in the home for men, working women, or housewives.

Table 2 also presents relative risks for marital status combined with the presence or absence of a child in the home. A child in the home was associated with lowered risk among married working women, a raised risk among married housewives, and unchanged risk among married men. Among the widowed, divorced and separated, a child in the home was associated with a lower mortality risk for both men and housewives and a higher risk among working women. Small numbers of individuals in subgroups yielded unstable estimates of these latter effects.

Although neither occupation nor number of children showed an increased mortality risk among employed women, further analyses were undertaken to detect possible interactions, as was done in the Framingham study.[18] There were no differences between clerical and non-clerical workers for any of the marital/parental status groups. The comparison between ever-married clerical workers who had children and those who did not yielded a relative risk of 1.6 (CI = 0.7, 3.9). We found no increased risk of mortality among clerical workers with either three, four, or more children.

Since marital and parental statuses affected mortality risk differentially for men and women, we fitted separate logistic models for ever-married men and each group of women, including many lifestyle risk factors (Table 3). As seen in the unadjusted estimates, widowed, divorced, or separated men with no child at home had 2.7 times the mortality risk of married men with no child at home (CI = 1.7, 4.5). There were too few widowed, divorced or separated men with a child at home to get a stable estimate of risk.

Among the working women, those formerly married who had a child in the home were 2.2 times more likely to die than were formerly married working women who did not have a child in the home, but the estimate was unstable (95% CI = 0.9, 5.5). The presence of a child had little effect upon mortality among married working women.

The logistic model for housewives revealed that married housewives with a child in the home had 2.2 (CI = 1.1, 4.4) times the mortality risk of married housewives with no child at home. In addition, housewives with four plus children had 1.9 (CI = 1.1, 3.3) times the risk of housewives with fewer or no children, even after controlling for other risk factors.

Discussion

In this prospective study, long-term employment by itself was not associated with mortality. Employed women

TABLE 2—Eighteen-Year Age-Adjusted Relative Risks of All Cause Mortality among Men, Working Women, and Housewives by Marital Status and Parenthood: Alameda County, 1965–82

Characteristics	Men			Working Women			Housewives		
	Risk	RR**	CI***	Risk	RR	CI	Risk	RR	CI
Marital Status									
Married	18.4	1.0	. . .	12.2	1.0	. . .	13.4	1.0	. . .
Single	26.5	1.4	0.9–2.1	14.0	1.1	0.6–2.2	. . .	. . .	. . .

Marital status among non-parents*** (formerly married/married)	2.7	(1.7–4.5)	0.7	(0.4–1.4)	1.6	(0.6–4.2)
Marital status among parents*** (formerly married/married)	0.4	(0.3–20.7)	2.3	(0.9–5.4)	2.1	(0.2–1.3)
Child in home among married*** (yes/no)	1.2	(0.8–1.7)	0.7	(0.3–1.4)	2.2	(1.1–4.4)
Child in home among unmarried*** (yes/no)	0.2	(0.1–1.6)	2.2	(0.9–5.5)	0.6	(0.2–2.4)
Physical health						
(disabled/healthy)	2.9	(1.7–5.0)	1.3	(0.6–3.2)	2.7	(1.2–5.6)
(conditions/healthy)	1.3	(0.9–1.8)	0.7	(0.4–1.5)	1.0	(0.5–1.9)
(symptoms/healthy)	1.1	(0.7–1.6)	0.7	(0.3–1.4)	0.4	(0.2–1.0)
Smoking status (current/noncurrent)	2.1	(1.6–2.8)	1.5	(0.9–2.5)	1.6	(0.9–2.7)
Alcohol consumption (heavy/light)	1.4	(1.0–1.9)	2.7	(1.2–5.9)	0.9	(0.4–2.2)
(abstain/light)	1.1	(0.8–1.7)	1.8	(1.0–3.3)	0.9	(0.5–1.9)
Life satisfaction (dissatisfied/satisfied)	1.1	(0.8–1.4)	1.7	(1.0–2.9)	1.0	(0.6–1.6)
Contacts with friends (few/many)	0.9	(0.6–1.2)	1.8	(1.1–3.1)	1.6	(1.0–2.7)
Number		1659		665		731

No significant ($p < 0.05$) independent increase in risk was found due to race, education, income, occupation (included for men only), physical activity, visits to a physician or financial strain.

*OR = odds ratio

**CI = confidence interval

***Model included interaction term for marital status and presence of child in the home

and housewives did not differ in mortality risk and both groups had only 70 per cent the risk of men. This finding is in agreement with most cross-sectional studies.[6,7,*,11,12]

Unlike the Framingham studies,[18,22] clerical workers were not at increased risk in this study. In addition, clerical workers who had ever-married and had children experienced no increased risk when compared to ever-married nonclerical workers with children.

The results of this study may disagree with those of Framingham, first because the outcome in this study was mortality from all causes, rather than the incidence of coronary heart disease. However, the leading cause of death for women is heart disease and 32 per cent of the deaths among women in this sample were due to heart disease. Second, Framingham women were more likely to have left school after only eight years of education (20 vs 13.5 per cent), more likely to be employed in blue collar jobs (43 vs 30 per cent), more likely to be single (18.6 vs 8.4 per cent), and less likely to be formerly married (19.4 vs. 26.3 per cent). These variables may influence who becomes and remains a clerical worker in some way that leads clerical workers to have higher relative risks than nonclerical workers in Framingham but not in Alameda County. Another difference is that the Framingham study categorized any woman as a housewife who did not have the necessary years of work experience so that many women with substantial years of work experience (but less than half of their adult lives) who were working at the time of the study were still categorized as housewives. In this study, housewives were women without the necessary years of work experience who identified themselves as housewives in 1965. This may explain why an effect of parenthood was found for housewives in Alameda County and not in Framingham.

The time period of this study (1965–82) was one of rapid change in women's roles, both at home and in the labor market. In order to minimize the problem of change in roles after measurement in 1965, three strategies were used. First, the analysis was restricted to people who were at least 35 in 1965. Twenty years ago most women had completed their childbearing by age 35, so little change would be expected in terms of having more children. Second, the measure of employment was a lifetime work history in which women had to have worked outside the home for at least one-half of the years since age 22. Third, we examined the results for older and younger women (35–49 and 50–65) separately, on the theory that changes in parenthood, marital status, and lifetime work would be more likely in the younger group. There were no differences between the two age groups.

This study indicates that the effects of marital status and parental status upon mortality in women cannot be considered independently, but the fear that working women with children will suffer such severe role overload and role conflict that their mortality risk will rise appears unfounded. Married working women with children had the lowest mortality risks of any role status group in this study. Neither the number of children nor having a child in the home showed any relation to mortality risk among working women except possibly in the case of single parents. Although we could speculate about the overwhelming demands of being a single parent, this is a finding of marginal significance. These women were single parents in 1965; since that time the divorce rate has risen dramatically, making the role of single parent much less deviant. This, plus the greater availability of support services, and other major social changes that have taken place since 1965, may mean that the demands of being a single employed parent have decreased somewhat, and reduced the association with mortality.

The most surprising findings in this study concerned

housewives, among whom having four or more children or a child present in the home appeared to increase risk. One possible explanation is that the relative risk of coronary heart disease for women whose first pregnancy occurred before age 24 is 1.8 compared to women who had never been pregnant or whose first pregnancy occurred later.[28] If housewives with more children had earlier first pregnancies our findings may reflect this association, but direct information concerning age at first pregnancy was unavailable.

The apparent negative impact of numerous children upon women's health, particularly that of housewives,[7,13,28–30] deserves systematic investigation. Merely looking at the number of children or whether a child is present in the home is not sufficient; rather the biological, social, and psychological concomitants of having children need to be investigated.

Since women with the largest number of roles—employed, married women with a child present in the home—had the lowest risk of mortality in this study and women with the fewest roles—unemployed, unmarried women with no child at home—had a greatly increased risk of mortality, this suggests that involvement in a multiplicity of roles at least is not harmful to women's mortality risk. On the other hand, mortality is an extreme outcome and multiple roles may have a negative impact upon morbidity. As roles or statuses become more specifically defined, it becomes harder to rank order them in terms of demands. Does the housewife with five children have more or fewer demands than the working woman with two children? Where do the formerly married fit in? To examine fully the effect of combining work, marriage, and parenthood, it is necessary to design studies which actually probe the demands, conflict, benefits, and gratifications of each role rather than attempting to infer these from occupancy of the roles and to account for the likelihood that the degree to which women have chosen their roles will influence the outcome.

APPENDIX
Categorization of 12 Variables Influencing Mortality: Alameda County, 1965–82

Variables	Categories	Remarks
Sociodemographic Variables		
Age	Years	
Race	White, Black, Other	
Education	0–8, 9–12, 13+ years	
Income	<$6,000, $6,001–9,999, $10,000–14,999, $15,000+	Household income adjusted for household size
Physical Health Variables		
Heath Status	No health problems, symptoms, chronic conditions, disability	Based on extensive list of questions concerning disability of movement and presence of chronic conditions, symptoms, and perceived energy levels
Physician Visits	0–9, 10+	Based on number of visits made to doctor during past 12 months
Health Behaviors		
Smoking Status	Current, not current	
Physical Activity	Inactive, active	Based on frequency of participation in five leisure time activities, swimming or walking, exercise, active sports, gardening, fishing or hunting and weighted by presumed energy expenditure
Alcohol Consumption	Abstain, light, heavy (≥drinks/month)	Based on frequency (number of times per week) and usual amount consumed
Psychosocial Variables		
Life Satisfaction	Dissatisfied, satisfied	Derived from nine questions concerning role satisfactions and feelings of pleasure in life
Contacts with Friends and Relatives	1–2 (few), 3–5 (many)	Derived from three questions on number of close friends and relatives and number of times seen per month
Financial Strain	0–4 (low), 5–7 (high)	Based on three questions asking about perceived strain with regard to income

Institute of Medicine Issues Call for Nominations for Lienhard Award

The Institute of Medicine is accepting nominations for the 4th annual Gustav O. Lienhard Award. The award, a medal and $25,000, recognizes individuals for outstanding achievement in improving personal health care services in the United States. The emphasis of the award is on creative or pioneering efforts that have appreciably improved personal health services rather than on the science base of health care. To encourage consideration of the widest possible range of candidates, there are no eligibility limits with respect to education and profession of individuals that may be nominated. Any individual or group may submit a nomination.

Names of nominees should be accompanied by a detailed written description of their accomplishments meriting this award. Only written material will be considered. Nominations must be postmarked by June 16, 1989, and should be submitted to:

Ms. Kay C. Harris
The Lienhard Award Committee
Institute of Medicine
2101 Constitution Avenue, NW
Washington, DC 20418

Support for the award is provided by the Robert Wood Johnson Foundation. Mr. Lienhard was chair of the Foundation's board of trustees from 1971 to 1987, a period in which the Foundation moved to the forefront of American philanthropy in health care. Previous recipients include: Julius B. Richmond, MD, architect of federal programs for Head Start and Neighborhood Health Centers in the 1960s and 1970s; Ernest W. Saward, MD, a pioneer in the establishment of prepaid group health plans; and Marie-Louise Ansak, a pioneer in nonprofit comprehensive care and founder of On Lok Senior Health Services, a day care center for the frail elderly.

Olfactory Function in Chemical Workers Exposed to Acrylate and Methacrylate Vapors

BRIAN S. SCHWARTZ, MD, RICHARD L. DOTY, PHD, CARL MONROE, MD, MPH, RICHARD FRYE, BA, AND SUE BARKER, RN

Abstract: An investigation of the olfactory function of 731 workers at a chemical facility which manufactures acrylates and methacrylates was undertaken using a standardized quantitative test. In a cross-sectional analysis of the data, no associations of chemical exposure with olfactory test scores were observed. A nested case-control study designed to evaluate the cumulative effects of exposure on olfactory function, however, revealed elevated crude exposure odds ratios (95% confidence interval) of 2.0 (1.1, 3.8) for all workers and 6.0 (1.7, 21.5) for workers who never smoked cigarettes. Logistic regression analysis, adjusting for multiple confounders, revealed exposure odds ratios of 2.8 (1.1, 7.0) and 13.5 (2.1, 87.6) in these same groups, respectively, and a dose-response relationship between olfactory dysfunction and cumulative exposure scores—semi-quantitative indices of lifetime exposure to the acrylates. The data also revealed decreasing exposure odds ratios with increasing duration since last exposure to these chemicals, suggesting that the effects may be reversible. (*Am J Public Health* 1989; 79:613–618.)

Introduction

A large body of animal toxicologic data indicates that many airborne chemicals can selectively damage cells within the olfactory neuroepithelium and/bulb, often in a specific and dose-related manner.[1–9] Depending on the chemical agent and the concentrations and durations of exposure, these changes may be either reversible or irreversible and may occur after either acute or chronic exposure.[6,9] Miller and others, for example, have reported that rats and mice exposed to ethyl acrylate, acrylic acid, and methyl methacrylate (5–300 ppm) evidenced, within the olfactory epithelium, respiratory metaplasia, squamous metaplasia, loss of olfactory neurons, hyperplasia of submucosal glandular elements, inflammation, degeneration, and focal necrosis.[10–13] These changes were dose-related to the severity and distribution of the damage and generally spared non-olfactory epithelia. A lower level of exposure below which damage consistently did not occur was not identified.

Despite these findings, the olfactory function of industrial workers exposed to such airborne chemicals has not been assessed, largely because an easy-to-administer and valid quantitative test of olfactory function has not, until recently, been available.[9,14,15] There are many cogent reasons why smell function should be assessed in the industrial setting:

- Normal olfactory function is important for worksite safety in a number of workplaces, e.g., during accidental leakage (odor detection thresholds can be lower than the level at which poisoning or explosion occurs).[9,16,17]
- Early detection of job-related changes in olfaction may allow reversal of detrimental effects (e.g., by decreasing exposure to the implicated agents).[18–23]
- Olfactory testing may be a useful addition to the neurotoxicologic testing armamentarium.[24,25] Quantitative tests of sensory and motor function have been employed but many of these tests require skilled technicians and are expensive, time-consuming, and invasive. Thus, the testing of olfactory function, as used in this investigation, has potential value in evaluating neurotoxicologic effects of chemicals that have detrimental effects on olfactory neurons and peripheral nerves; this testing is easy to perform, reliable, rapid, quantitative, and comparatively inexpensive.[15,26,27] Normative data are now available from thousands of subjects.[26]

The present study was undertaken to test the hypothesis that airborne ethyl acrylate, acrylic acid, and methyl methacrylate (all chemicals implicated to cause olfactory epithelial destruction in animals) cause a decrement in olfactory function in chemical workers after acute or chronic exposure. Both cross-sectional and nested case-control studies were performed.

Methods

Study Population

The study population consisted of all employees at a large manufacturing facility of the Rohm and Haas Company. The plant employs 909 workers in a variety of job activities and manufactures a number of chemicals, including acrylic acid and a variety of acrylates and methacrylates (especially ethyl acrylate, butyl acrylate, and methyl methacrylate). The facility operates 24 hours a day on three shifts. Participation in the study was voluntary, but encouraged through plant publicity from December 1986 to February 1987. Testing was conducted during two weeks in February 1987.

Approximately 850 of the 909 plant employees were available for testing during the two-week study period. The 59 workers who were unavailable for testing included workers absent for long-term disability, illness, and vacation. Of these 850 persons, 731 were tested; 710 (83 per cent of

available employees, 78 per cent of total employees) were full-time Rohm and Haas employees, and 21 were contractors or consultants who happened to be on location during the testing period and desired to participate. The participants included 618 males and 113 females, ranging in age from 17–69 years (mean 42.9 years, SD = 11.3 years). The test group included 596 Whites, 98 Blacks, and 37 persons of Asian or Hispanic ethnicity. The subjects were from all three work shifts: 526 day shift, 131 evening shift, and 74 night shift.

Data Collection

The testing consisted of administering the University of Pennsylvania Smell Identification Test,* a questionnaire contained within the UPSIT, and a brief questionnaire to obtain shift and job information. The UPSIT consists of four booklets, each containing 10 microencapsulated odorants positioned on brown strips on the bottom of each test page.[14,26] The test is self-administered by scratching a pencil tip over the odorant label strip on the bottom of the page to release the fragrance, smelling the label, and choosing the perceived odor from four multiple choice answers. The test is forced-choice; the subject is required to choose one of the four answers even if no smell is perceived. The test is highly reliable and correlates with more lengthy test procedures.[14,27] Development of the UPSIT, as well as its relation to age, gender, and other factors, is described elsewhere.[14,26–29]

The test questionnaire obtained information on these study variables: age, gender, ethnic group, smoking history and dose, educational level, history of medical problems (self-reported problems which required treatment), history of smell or taste dysfunction, current medications, and work shift information. Detailed current job information was provided by the plant personnel office for all workers, and detailed employment histories were provided for the 154 workers in the nested case-control study.

Study Design

A cross-sectional (prevalence) study of olfactory function in chemical workers was undertaken which considered only current jobs and exposures. Next, a nested case-control study was performed to assess the cumulative effects of the chemicals of interest (see next section) on olfactory function. To be eligible for the case-control study, all cases and controls had to be full-time employees of Rohm and Haas for at least the past six months. Cases (N = 77) were defined as subjects scoring at or below the tenth percentile (for their age) on the UPSIT in 10 five-year age strata: ages 21–25, 26–30, 31–35, 36–40, 41–45, 46–50, 51–55, 56–60, 61–65, and 66–70 years. These cases were matched 1:1 to a random sample of controls defined as subjects scoring at or above the 50th percentile, for their age, in these same age strata. Cases and controls were matched on gender, ethnic group, and age.

It should be noted that the atypical selection of controls in this study (restricting eligible controls to the top half of their distribution) was designed to increase our ability to detect an association between chemical exposure and olfactory dysfunction if one existed. The design would tend to exaggerate the association (compared to a design using all non-cases as eligible controls, as is typically done) only if it existed; if no association between exposure and olfactory function existed, there would not be an increased risk of detecting one (i.e., no increased risk of a type I error).

Definition of Exposure

In the cross-sectional study, workers were classified into one of four exposure categories based on current job only:

- no significant chemical exposures (N = 319),
- exposure to chemicals other than acrylic acid, methacrylic acid, acrylates, or methacrylates (N = 193),
- exposure to lower levels of acrylic acid, methacrylic acid, acrylates, or methacrylates (N = 164),
- exposure to higher levels of acrylic acid, methacrylic acid, acrylates, or methacrylates (N = 55).

The foundation for the classification of workers into the lower and higher acrylate/methacrylate categories relied on the distinction between an Operator I and an Operator II in this plant. Those in the Operator I category spend most of their time in a ventilated control room monitoring the chemical process with little time spent outdoors on the chemical columns supervising workers or taking samples. An Operator II employee works primarily outdoors on the chemical columns taking samples and performing other duties. Industrial hygiene data collected in the plant from 1978–85 confirmed that Operator II employees and pumpers had the highest chemical exposure among workers in the plant. Pumpers work mainly to pump materials into and out of containers for shipping or receiving; during the opening of valves and lines for this purpose, high local concentrations ensue. When the distinction was unclear between Operator I and II in certain areas of the plant, Job Exposure Profiles and the aforementioned industrial hygiene data were used to classify workers into the lower and higher exposure categories. Job Exposure Profiles, developed by plant industrial hygienists, detail the chemicals worked with and the concentrations of exposure for many jobs in the plant, and thus were useful in this semi-quantitative assignment of exposure status. Finally, plant and corporate industrial hygienists helped to classify jobs whose categorization was unclear after the above steps were taken. These jobs were primarily ones at other Rohm and Haas plants and were approximately evenly distributed among the four exposure categories.

In the case-control study, exposure was studied in three ways:

- Exposure expressed as "never" or "ever" employed in job category 3 or 4 above for at least six weeks;
- the total duration of employment at the plant analyzed as a continuous variable; and
- a cumulative exposure score for each worker, analyzed as a continuous variable. The cumulative score was calculated by classifying each job title the worker ever held into one of the four exposure categories outlined above, multiplying the duration of time employed in each job title by the score for that job title, and adding these for all job titles ever held at the plant. The first two categories—no exposure and other chemical exposure—were assigned a score of zero, the lower acrylate/methacrylate category a score of one, and the higher acrylate/methacrylate category a score of two.

Current ethyl acrylate and acrylic acid levels varied from 0.01 ppm to 56 ppm; most areas of the plant have levels (as eight hour time-weighted averages) well below the threshold limit values (TLV) recommended by the American Conference of Governmental Industrial Hygienists of 10 parts per million (ppm) for acrylic acid and 5 ppm for ethyl acrylate,

*UPSIT; commercially available as the Smell Identification Test™, Sensonics, Inc, Haddonfield, NJ.

both as eight hour time-weighted averages. The highest levels were found when chemicals were pumped into containers for shipping, or when lines were opened for new connections or to obtain samples. Much of the available industrial hygiene data were for these specific high-exposure tasks (5–40 minute samples) and revealed levels at the high end of the aforementioned range. Current levels were used in determining exposure scores.

Analysis

Data analysis was performed on a microcomputer with the BMDP Statistical Software program. After detailed descriptive analyses, including frequencies and cross-tabulations, a three-way analysis of covariance with two covariates was used as the main model for the cross-sectional study.

In the case-control study, matched crude exposure odds ratios were calculated by discordant pairs,[30,31] and then conditional logistic regression was performed to calculate an adjusted exposure odds ratio. These two results were very similar to those calculated in unmatched analyses, so the matches were broken for the remainder of the data analysis. The only matched analysis results presented are the crude exposure odds ratio and a discordant pair table. In the unmatched analyses, crude odds ratios were calculated for all study variables, and then the Mantel-Haenszel procedure was used to calculate summary statistics after stratification by important confounders.[30,31] Logistic regression was then employed to adjust for other study variables in the calculation of the adjusted exposure odds ratio.

The nested case-control study examined three groups of workers: the entire group of cases and controls; only cases and controls who never smoked cigarettes; and cases redefined as those with UPSIT scores below 30 compared to all controls. The definition of cases below the tenth percentile by age allowed some cases with UPSIT scores as high as 35 out of 40; therefore, it was important to evaluate the worst-performing cases separately. A score of 30 or less on the UPSIT represents significant diminution of olfactory ability;[14] for example, based on normative data from thousands of subjects,[26] the approximate tenth percentile of performance on the UPSIT in the age range 16–50 years old is 34 for females and 33 for males.

Results

The cross-sectional analysis revealed mean (95% confidence interval) UPSIT scores of 37.8 (37.5, 38.0), 37.4 (37.0, 37.7), 37.0 (36.6, 37.5), and 37.6 (36.9, 38.1) in the none, other, lower acrylate/methacrylate, and higher acrylate/methacrylate exposure groups, respectively. The main model (three-way analysis of variance with two covariates) included ethnic group (White, Black, other), smoking status (never, previous, current), and exposure category (none, other chemicals, lower acrylates, higher acrylates) as grouping factors, and age and age-squared as covariates. This analysis revealed no differences in UPSIT scores in the four exposure groups ($F = 2.19$, $df = 3/698$, $p = 0.09$) after control of confounding by these variables.

Characteristics of cases and controls can be found in Table 1. There were apparent differences in the smoking history and ethnic categories. Results of the crude matched analysis are presented in Table 2. In the unmatched analysis, the case-control study revealed elevated crude exposure odds ratios for all workers and for never smokers (Table 3). A crude exposure odds ratio (95% CI) of 2.6 (1.2, 6.0) was found for cases with UPSIT scores below 30 (worst-performing cases (N = 34) compared to all controls, N = 111). Table 3 also shows the 2×2 contingency tables after stratification by smoking status. Effect modification appears to be present, with a markedly elevated exposure odds ratio in the never smoking group.

The logistic regression model used to adjust for confounding included all the measured independent variables and the matching variables: chemical exposure, smoking status (three categories), ethnic group (three categories), medications, age, history of smell dysfunction, history of medical problems, level of education, gender, and work shift tested. This model was then applied to the three groups of workers outlined above. There were no significant interactions with the exposure variable in this model for any of the three groups of workers. Control of all confounders with logistic regression revealed adjusted odds ratios of 2.8 (1.1,

7.0) for all workers (N = 141), 13.5 (2.1, 87.6) for never smokers (N = 57), and 2.9 (0.8, 11.3) for cases with UPSIT scores below 30 (N = 101). The most important confounders were smoking status, self-reported smell dysfunction, and educational level. The adjusted estimate of the overall exposure odds ratio was insensitive to changes in the method of controlling for smoking in the logistic regression model, e.g., when smoking was changed from a categorical variable to a continuous variable (in pack-years).

A summary of the data suggesting a dose-response relationship between olfactory dysfunction and the cumulative exposure score can be found in Table 4. Examination of these data reveals increasing exposure odds ratios as the cumulative exposure score increases, then a decrease in this odds ratio in the highest category of exposure.

Many employees worked in different areas of the plant where other chemicals were manufactured and acrylates and methacrylates were not used. In an attempt to control for the effects of other chemical exposures, a surrogate for exposure to these chemicals was calculated as years ever employed in other sections of the plant for all workers. The results of logistic regression analyses controlling for years employed in other areas of the plant, as well as all other measured independent variables, are presented in Table 5. There appears to be no confounding by these variables.

Finally, a summary of the data examining the reversibility of the olfactory dysfunction associated with these chemicals can be found in Table 6. The decreasing exposure odds ratios as duration since exposure increases suggests that the olfactory dysfunction associated with chemical exposure may be reversible. This finding is not entirely consistent, however, as can be seen by the adjusted odds ratios in Table 6. It should be noted that the categories in Table 6 were chosen for illustrative purposes; the results did not change when other cutpoints were chosen or when the year since last exposed variable was included in the models as a continuous variable.

Discussion

This study evaluated exposure to acrylate and methacrylate vapors in prevalent cases of olfactory dysfunction and controls without olfactory dysfunction. There are many potential problems in such use of prevalence data in epidemiologic research.[31] Speaking in general terms, it is well known that numerous factors can influence the prevalence of disease (a generic term for the effect under study), such as disease duration and severity, that do not influence other effect measures such as risk or incidence. The association between exposure and disease can also be artifactual if disease duration is not identical in exposed and unexposed cases or if disease affects exposure status. The bias introduced by these factors can be in either direction (increasing or decreasing the real association) and is not predictable in this study. Review of employment records revealed evidence that persons employed in this plant enter one area (cyanhydrin, acetylene, acrylate, etc., processes with different physical areas in the plant) and stay in that area in various jobs for their entire career. This would argue against olfactory dysfunction being a prime determinant of exposure status.

The finding of the highest relative risk of olfactory dysfunction in the never smoking group is consistent with many plausible biological hypotheses. These subjects were

‡Standard error of beat coefficient

not exposed to the insult of cigarette smoking on olfactory function, and thus would be expected to be at the highest risk for olfactory dysfunction from chemical exposure if this exposure caused olfactory dysfunction. This relative risk is substantial, with an odds ratio of 6.0 in the crude analysis and 13.5 in the adjusted analysis.

The cross-sectional study is best suited to evaluate the effects of recent exposure to these chemicals, and did not suggest any association between current job and olfactory dysfunction. The mean UPSIT score in the highest exposure group was virtually identical to the mean score in the non-exposed group. However, the nested case-control study, designed to evaluate the cumulative effects of lifetime exposure, revealed consistently elevated exposure odds ratios in many different groups even after control for confounding. The dichotomized exposure variable (ever or never exposed) and the cumulative exposure score can be criticized as being crude measures of exposure; however, these categorizations are likely to cause a nondifferential misclassification of exposure, which would tend to bias our findings toward the null.[31] Also, the assumption that specific jobs in the plant during the 1950s and 1960s had the same exposure levels as current jobs is unlikely to be true; again, this is a nondifferential misclassification of exposure. Finally, the definition of cases in this study as below the tenth percentile for their age in the cohort can be criticized as an arbitrary cut-off. This cut-off is also more likely to bias our results toward the null. In fact, when the analyses were repeated including just the worst-performing cases (those with UPSIT scores below 30), the crude exposure odds ratio was higher than for the overall group (the crude exposure odds ratio was 2.0 overall and 2.6 for the worst-performing cases); however, the adjusted estimate was unchanged.

The association between exposure and relative risk of disease is supported by the apparent finding of the dose-response nature of this relationship. The reduction in risk in the highest category of exposure remains unexplained. It may reflect a leveling-off rather than a reduction of risk, but further studies are necessary to clarify this finding. This dose-response relationship was not observed when duration of employment was substituted for the cumulative score in the logistic regression model. This important finding supports the contention that the cumulative score variable was not just a surrogate for duration of employment, but rather reflected a weighted score of exposure to the chemicals of interest. The finding of decreasing odds ratios with increasing duration since exposure is also consistent with many biological hypotheses; however, caution should be used in interpreting the meaning of this finding. Evidence obtained from prospective studies of olfactory function after exposure to these chemicals would be needed to conclude that the effects are reversible.

It should be noted that the plant manufactures a number of chemicals other than the acrylates/methacrylates to which workers are exposed. These other exposures were not measured but were controlled for in the analyses by controlling for years of employment in other areas of the plant. This method of controlling for other chemical exposures is acknowledged to be crude; it was the best method with the available data. The fact that the adjusted exposure odds ratio did not change after including these variables in the model reveals the absence of confounding by these "other exposures" variables. This was not surprising in view of the fact that workers in this plant tend to work in one area during their career; thus, work in other areas cannot be associated with exposure to acrylates/methacrylates, a necessary condition for confounding. It is possible, however, given the crude method of controlling for them, that other chemicals in the plant may be responsible for, or contribute to, the observed decrement in olfactory ability, alone or in combination with the acrylates/methacrylates.

As participation was voluntary, the 80 per cent participation could lead to another source of error in estimating the relation between exposure and olfactory dysfunction. The direction of this bias may be either to increase or decrease the association between exposure and olfactory dysfunction. This bias was evaluated by examining the jobs of the nonparticipants; with one exception, these jobs seemed to be a random distribution of nonparticipation by job title. The exception was that many workers employed in the mechanical group (electricians, pipefitters, carpenters, painters, etc.), approximately 40 per cent, chose not to participate. The mechanical group is a large, diverse group of workers, including those exposed and unexposed to acrylates/methacrylates. Although not obviously present, self-selection bias is a well-recognized occurrence in studies of this type.[31]

There is a large body of literature on olfactory dysfunction in humans secondary to chemical exposure; approximately 120 chemicals have been implicated to cause such dysfunction.[9,23] Most of the published studies are case reports or case series, few measure exposure quantitatively, and none employ rigorous epidemiologic methods. The studies that do measure exposure quantitatively suggest that hyposmia or anosmia only result from exposure to concentrations above the threshold limit value (TLV).[9,17] In the present study, the uncertainty in the exposure levels before monitoring began in 1978 causes difficulty in attributing the observed changes in olfactory function to a given exposure limit. This study cannot evaluate the effects of exposures orders of magnitude below the TLV (as may be encountered with environmental exposure). What is known about the physiology of the olfactory epithelium and its mucosal barrier would suggest that a threshold to the effects of chemicals may exist, in that this mucosal barrier absorbs and possibly degrades low levels of chemicals before they reach the olfactory neuroepithelium itself.

There are many points in the olfactory pathway that may be affected by exposure to these chemicals, and many pathophysiologic mechanisms may be postulated. The animal data revealed that exposure to acrylate and methacrylate vapors caused loss of olfactory neurons (neurotoxicity) as well as changes in the olfactory mucosa. The present study cannot determine the exact site of action of this exposure in humans; it may be caused by changes in the receptor site or

mucosa, neurotoxic effects, or central nervous system effects (olfactory bulb or pyriform, prepyriform, and entorhinal cortices). The animal data suggest that the most likely site is the olfactory mucosa or primary olfactory neuron.

Although this study suggested that exposure to acrylates and methacrylates is associated with a decrement in olfactory ability, as measured by a standard test of olfaction, it should be noted that this impairment is physiologic, but often not clinical. It is known that UPSIT scores in the range observed in the cases in this study are associated with a diminished ability to smell a number of environmental chemicals. The degree to which these changes effect the quality of life, lead to a decreased ability to perform job duties, or increase the risk of injury in areas where olfaction may be an early warning system for escape from hazardous airborne chemicals is unknown. The results of this work suggest that medical surveillance should be instituted to: clarify the effects of low-level exposure; determine the adequacy of the current exposure limits; determine whether the effects are reversible; and determine to what degree decreased olfactory ability affects quality of life and job safety.

Hearing Loss among High School Farm Students

STEVEN K. BROSTE, MS, DONALD A. HANSEN, MS, RICHARD L. STRAND, MS, AND DEAN T. STUELAND, MD

Abstract: To study the prevalence of hearing loss among teen-aged farm children in central Wisconsin, audiometric threshold testing of 872 vocational agriculture students was carried out over a three-year period. The results indicate an increased prevalence of hearing loss among students actively involved in farm work, as compared to their peers not involved in farm work. Findings also suggest that use of hearing protection may reduce the risk of hearing loss among students who work on the farm, although few students report the use of such devices. These data also suggest that the hearing loss often observed in adult farmers may begin in childhood. (*Am J Public Health* 1989; 79:619–622.)

Introduction

Farmers are exposed to many sources of noise, often continuing for long periods of time at levels that are potentially damaging to hearing. A number of studies have suggested that farmers have higher than expected rates of hearing loss.[1–8] Many of these studies did not employ controls, while others have a built-in bias due to self-selection of subjects. Nevertheless, it is believed that the adult farm population suffers an increased risk of hearing loss, largely due to occupational noise exposure.

The present study was undertaken to determine whether there was greater evidence of early hearing loss among high school students engaged in farming than among students not involved in farming. A further goal was to describe sources of noise to which farm students are exposed, and to study the associations between various sources of noise, subject characteristics, and prevalence of early hearing loss.

Methods

From October 1985 through May 1988, audiologists from the Marshfield Clinic, Marshfield, Wisconsin, visited 12 area high schools to do audiometric threshold testing of vocational agriculture students. Students tested were between 12 and 19 years of age. Although all students were from vocational agriculture classes, they represented a wide range of participation in farming operations, from living and working more than 40 hours per week on the farm, to living in town and having no exposure to farm work. All students and their parents were asked to complete a brief questionnaire on health and hearing history, history of exposure to noisy farm and recreational equipment, and degree of participation in farm work. They were also asked to give their signed, informed consent to the testing procedures. At most schools, the entire class participated, except for the few students who were absent. To prevent temporary threshold shifts due to recent noise exposure, the audiologist described the project to the class and distributed ear plugs prior to testing. The students were instructed in the use of the ear plugs, and asked to use them when involved in any noisy activity either the night before or the day of testing. The vocational agriculture teachers encouraged complete participation, and later took responsibility for distribution of ear plugs to be used prior to testing. Each school was visited once per school year and many of the students were tested more than once during the 1985–88 period. For this report, only the first examination for each student was used, resulting in a total of 872 audiograms. Findings from subsequent audiograms collected in an ongoing longitudinal study will be described in a future report.

Testing was performed in a truck-mounted mobile testing unit with two specially designed Industrial Acoustics Corporation mini-testing booths. A Quest bioacoustic simulator, Model BA 201-25, was used for daily monitoring of background noise levels, and a General Radio octave band sound level meter, Model 1933, was used for assessing background noise levels. Two Maico manual audiometers, Model MA-39 with TDN-39 10 ohm earphones, were used for air conduction threshold testing. Regular electronic calibrations were conducted on each audiometer to ANSI-1969 standards.

A Hughson-Westlake modification of the ascending method threshold technique[9] was utilized for determining hearing levels. Hearing threshold was defined as where the tone was heard almost 100 per cent of the time and below which the tone was almost never heard. To minimize biases due to the learning effect, tones were presented in random fashion, both for ear tested and audiometric frequency (250, 500, 1000, 2000, 3000, 4000, 6000 and 8000 Hertz).

Analysis

For purposes of data tabulation, students were classified prior to testing into four distinct farming exposure groups based on their responses to the questionnaire and follow-up inquiries by the audiologist. These groups were:

- individuals who lived on farms and participated in virtually all farming activities (group A),
- individuals who did not live on farms, but worked on a farm either for hire or to help relatives or friends (group B),
- individuals who lived on farms, but did not participate or had minimal participation in chores and other farming operations (group C), and
- individuals who did not live on farms, and had little or no direct involvement with farm work (group D).

Hearing threshold values of 10 dB or less were classified as normal for each of the eight frequencies tested, and levels higher than 10 dB were classified as abnormal. This level was chosen based on a number of previous studies in similar age groups.[10–12] If a student had normal hearing (≤10 dB) at both 500 and 1000 Hertz, and abnormal findings (>10 dB) in the same ear at either 4000 or 6000 Hertz, he or she was

considered to show evidence of early noise-induced hearing loss. A number of authors have suggested that this pattern of loss in the higher frequencies represents the early stages of noise-induced hearing loss.[4,8,13–15] This definition assigns subjects having below normal hearing at both low and high frequencies to the normal group, since this pattern is thought to be more characteristic of hearing loss secondary to illness or a middle ear disorder. Also, 26 subjects with mild hearing loss at low frequencies and more severe loss at high frequencies were classified as normal, and all but two of these possible misclassifications were in the groups with the most farm noise exposure (groups A and B).

Associations between demographic factors, sources of noise exposure, and prevalence of hearing loss were summarized using the odds ratio.[16] For multivariate analyses, logistic regression was used to estimate the odds ratio and its 95 per cent confidence intervals,[17] controlling for other relevant factors.

Results

Characteristics of the four farming exposure groups are shown in Table 1. The two groups with significant farm work exposure (labeled A and B) consisted primarily of males. The group reporting living on the farm, but having little involvement with farm work (labeled C) consisted primarily of females. Detailed probing by the audiologist of reported equipment use often revealed that some exposures were only occasional or secondary, as in the case of chain saws, where the student was frequently only a bystander, perhaps stacking or splitting wood. As another example, rifle use was often confined to the short deer hunting season and not a frequent activity. Although many of the responses to the questions on noise exposure shown in Table 1 are not thought to be reliable, collectively they suggest that the four exposure groups are similar with regard to health history, and that they differ markedly in the overall degree of exposure to noisy farm and recreational equipment.

Figure 1 displays the per cent of subjects in each of the four farming exposure groups who exhibit right ear hearing loss. At each frequency tested there was a higher rate of hearing loss in groups A and B, those with the most exposure to farm work. The differences (A/B vs C/D) are most marked at high frequencies. Similar results were found in both males and females, and also when hearing loss was defined as having threshold levels in excess of 20 dB (Figure 2). Hearing loss at the higher frequencies was observed even more often in the left ear.*

The percentages of students found to have evidence of hearing loss in at least one ear at either high or low frequencies were 71 per cent, 74 per cent, 36 per cent, and 46 per cent for groups A, B, C and D, respectively. Hearing loss in only low frequencies (500 or 1000 Hz) was uncommon, occurring in less than 5 per cent of the students. Hearing loss in only high frequencies (4000 or 6000 Hz) was much more common, occurring in nearly half of the students involved in farming (groups A and B) and in approximately one-fourth of the students not involved in farming (groups C and D). Hearing loss in both high and low frequencies was very infrequent in groups C and D, but was present in 13 per cent of right ears and 13 per cent of left ears in groups A and B combined.

Table 2 shows the prevalence of the combination of normal hearing in the low frequencies and hearing loss in the high frequencies, which we have labeled noise-induced hearing loss. The highest prevalence rates were found in the two groups most involved in farm work, with rates in groups A and B roughly twice those in groups C and D. The left ear was most frequently affected in group A, the students living and working on the farm, but there was little difference between left and right ear prevalence rates for the other groups. The prevalence of noise-induced hearing loss did not vary appreciably by month or by school.

Preliminary data from the ongoing longitudinal study indicate that the hearing deficits observed in the first year persist into the second year. On retesting one year later of students in groups A and B who were classified as having noise-induced hearing loss, 17 per cent had reverted to

normal, versus 26 per cent of groups C and D. Of those previously classified as normal, 37 per cent of the students in groups A and B were classified as having hearing loss in the second year, versus 17 per cent in groups C and D. Overall, prevalence in groups A and B increased from 56 per cent to 63 per cent, and in groups C and D from 35 per cent to 37 per cent. When hearing threshold levels showed improvement, it was only rarely by more than five dB.

for the effects of age, sex, family history of hearing loss, and use of amplified music and snowmobiles or motorcycles. Memberships in groups A and B were most strongly associated with prevalence of noise-induced hearing loss. The estimated odds ratio of group A students to group D students was 2.5, as compared to an unadjusted odds ratio of 2.7. The estimated odds ratio of group B to group D students was 2.3, compared to the unadjusted ratio of 2.4. The analysis suggested that group C subjects were at a lower risk for noise-induced hearing loss than group D, but the confidence limits for this odds ratio include 1. Other variables included in this model appear to have only weak associations with prevalence of noise-induced hearing loss.

To further study the role of various sources of noise on prevalence of hearing loss, a separate logistic regression analysis is shown in Table 4 for students most heavily involved in farming operations (groups A and B). Students in group A had a slightly increased odds of hearing loss over students in group B, confirming the univariate results shown earlier (Table 2). Use of snowmobiles or motorcycles was associated with a slight but unstable increased odds of hearing loss, and the reverse was true with barncleaners. Use of hearing protection was suggestively associated with a reduced odds of noise-induced hearing loss, with an estimated odds ratio of .61 (95% CI = .34, 1.09).

Previous studies[1–4] have implicated tractor driving as a cause of hearing loss in farmers. Therefore another regression examined the subgroup of students in groups A and B who reported tractor use.* Most results parallel those shown earlier, but use of hearing protection in this group showed a more pronounced protective effect (O.R. = .53, 95% CI = .29, .96).

Discussion

Our data suggest that teenaged school children who are actively involved in farm work have increased prevalence of mild hearing loss and early noise-induced hearing loss (de-

*Data available on request to author.

fined as normal hearing at low frequencies combined with hearing loss in the high frequencies). Our results (coupled with reports of increased hearing loss in adult farmers) suggest that adult hearing loss may begin in childhood. Many farm children spend time in the vicinity of noisy machinery from an early age, including riding on and operating tractors and combines. In a small pilot study at our institution, we measured sound levels of tractors and other farm implements and found noise levels of many to be at or above levels for chronic exposure considered to be potentially damaging by current standards. Of 31 tractors tested at ear level in the driver's seat, without cabs or with a cab with an open window, only one tractor produced less than 85 dB at full throttle. Six of these tractors produced sound levels of 95 dB or more. As of this writing, OSHA (Occupational Safety and Health Administration) standards for maximum length of daily exposure to continuous or intermittent noise are eight hours at 85 dB and four hours at 95 dB. It is important to note that these standards are primarily meant to apply to adults. In addition to the noisy farm implements, people living in rural areas frequently make use of noisy recreational equipment such as firearms, power tools, snowmobiles, and motorcycles.

Our findings of greater left ear loss among farm students confirm those of other studies.[12,13,18,19] In the case of tractor drivers, it has been observed that the left ear is more likely to be exposed to engine noise, as drivers habitually observe their work by looking over their right shoulder, thereby shielding the right ear by the head shadow.[13]

The observed associations between the subject characteristics and prevalence of noise-induced hearing loss may have been affected by misclassification of farm students with significant noise-induced hearing loss into the normal group, due to the requirement that there be normal hearing at low frequencies. Also, the use of noisy equipment was recorded as a dichotomous variable, so that rare or occasional use of a piece of equipment was given equal weight to equipment used very frequently. Both of these sources of misclassification would be expected to weaken the observed associations. A third factor, for which we did not attempt to account, is the relation between the reported uses of the various farm implements. A student may typically be assigned a set of chores that could require the use of certain pieces of equipment and preclude the use of others. If there is much variation in the farm machinery used from student to student, and if most are significant sources of noise, the association of specific pieces of equipment with hearing loss would be difficult to untangle. It is also likely that even though students may not report operating certain pieces of equipment, they may have ridden on and been exposed to noise from these machines from an early age. The foregoing may explain the lack of any strong associations between reported use of farm equipment and prevalence of noise-induced hearing loss.

Aside from not participating in farm work, there are essentially two practical means presently available to reduce noise exposure on the farm. The first is use of hearing protection devices. Only 9 per cent of the farm students tested reported use of hearing protection when working in noisy areas; yet the evidence that students using hearing protection have a lower prevalence of hearing loss suggests there may be great potential for preventive efforts in this age group. A second means to reduce noise exposure is proper use of tractor and implement cabs. In our sample, only seven of the 563 tractor drivers exclusively used tractors with cabs. Our pilot study of noise levels found that tractors with cabs were less noisy, and that if the cab windows were closed, noise levels were reduced an average of seven dB more than if the windows were open. The present study showed only a weak protective effect of tractor cabs, however.

With the economic pressures facing many farmers, exposure of children to noisy and hazardous machinery could be expected to increase. Adolescent and teen-aged children often fill roles previously held by hired help. As farmers and their spouses take jobs off the farm to supplement income, farm children take on increasing responsibility for farm operations, and may be at increasing risk of hearing loss and other occupational health hazards of farming.

ACKNOWLEDGMENTS

Preliminary results of this study were presented at the National Rural Health Association Meeting, May 20, 1988, and at the 116th annual meeting of the American Public Health Association in Boston, November 13–17, 1988. This research was supported in large part by a donation from WD Connor to the National Farm Medicine Center. We wish to thank Brian Weiler, Amy Schultz, Dawn Lingford, and Laura Brand for data processing and manuscript preparation. James Holt, MD, provided the information on noise levels. We also wish to thank the vocational agriculture instructors and students from the high schools which participated in the study.

Respiratory Disease Associated with Community Air Pollution and a Steel Mill, Utah Valley

C. Arden Pope III, PhD

Abstract: This study assessed the association between hospital admissions and fine particulate pollution (PM_{10}) in Utah Valley during the period April 1985–February 1988. This time period included the closure and reopening of the local steel mill, the primary source of PM_{10}. An association between elevated PM_{10} levels and hospital admissions for pneumonia, pleurisy, bronchitis, and asthma was observed. During months when 24-hour PM_{10} levels exceeded 150 $\mu g/m^3$, average admissions for children nearly tripled; in adults, the increase in admissions was 44 per cent. During months with mean PM_{10} levels greater than or equal to 50 $\mu g/m^3$ average admissions for children and adults increased by 89 and 47 per cent, respectively. During the winter months when the steel mill was open, PM_{10} levels were nearly double the levels experienced during the winter months when the mill was closed. This occurred even though relatively stagnant air was experienced during the winter the mill was closed. Children's admissions were two to three times higher during the winters when the mill was open compared to when it was closed. Regression analysis also revealed that PM_{10} levels were strongly correlated with hospital admissions. They were more strongly correlated with children's admissions than with adult admissions and were more strongly correlated with admissions for bronchitis and asthma than with admissions for pneumonia and pleurisy. (*Am J Public Health* 1989; 79:623–628.)

Introduction

On March 20, 1984, the US Environmental Protection Agency (EPA) proposed changes in the national ambient air quality standards for particulate pollution. Total suspended particulates (TSP) was to be replaced with a new indicator of particulate pollution that includes only those particulates with an aerodynamic diameter equal to or less than a nominal 10 micrometers (PM_{10}). On July 1, 1987, the EPA announced its final decision. The previous primary TSP standards were to be replaced, effective July 31, 1987, with a 24-hour PM_{10} standard of 150 micrograms per cubic meter ($\mu g/m^3$) with no more than one expected exceedance per year and an annual PM_{10} standard of an expected arithmetic mean of 50 $\mu g/m^3$.[1]

Earlier studies of the health effects of particulate pollution[2–8] revealed a possible connection between air pollution and human health, and launched a wave of research exploring this connection.[9–19] Recent research has observed that even moderately elevated concentrations of particulate pollution may result in reductions in children's pulmonary function[20,21] and increased risk for bronchitis and other respiratory illnesses.[22] Other recent research questions the existence of a threshold level.[1,23]

Previous studies have not used PM_{10} as an indicator of particulate pollution. Recent experiences in Utah County have provided a unique opportunity to investigate a possible association between respiratory health and different levels of PM_{10}. Utah Valley has had daily monitoring of PM_{10} since April 1985; it has an extremely low percentage of smokers; it has experienced a prolonged shut-down and then reopening of the steel mill, its largest source of particulate pollution; over time, since monitoring of PM_{10} began, the valley has experienced considerable variability in levels of fine particulate pollution; and hospital inpatient admissions data for respiratory illnesses can be obtained. The objective of this paper is to report what has been observed in Utah Valley with respect to hospital admissions for respiratory illnesses and PM_{10} levels.

Methods

Study Area

Utah Valley, located in Utah County of Central Utah, is the third largest county in the state with a population of 258,000 in 1987.[24] Approximately two-thirds of the population resides in five nearly contiguous cities situated on a valley floor with an elevation of approximately 1,402 meters above sea level bordered east and west by mountains (Figure 1).

Based on an unpublished 1986 Utah State Department of Health survey, only 5.5 per cent of Utah County's adults (18 years of age or older) smoke; approximately 90 per cent of its

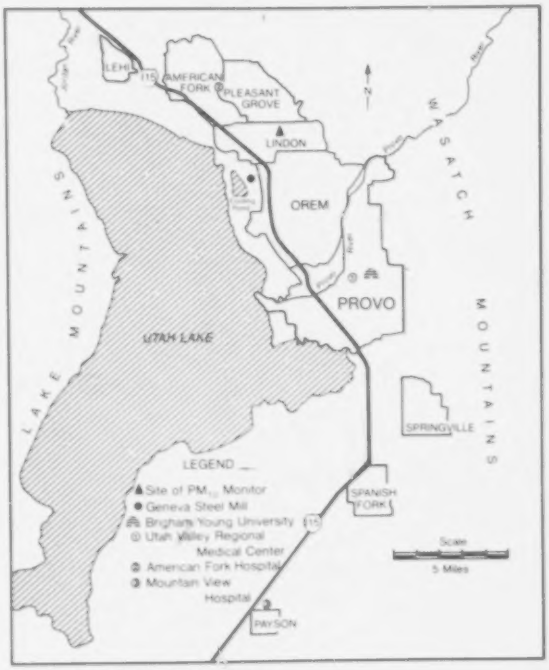

FIGURE 1—Study Area, Utah Valley

residents are members of the Church of Jesus Christ of Latter-Day Saints (Mormon)[25,26] which has strong church teachings against smoking.

Monitoring of particulate pollution began in 1964 and for carbon monoxide in 1971. On March 3, 1978, the EPA designated the county as a non-attainment area in accordance with provisions of Section 107 of the Clean Air Act. EPA ambient air quality standards for TSP and carbon monoxide were often exceeded at monitoring sites at Provo, Lindon, and Pleasant Grove during winter months when temperature inversions trapped emissions in stagnant air near the valley floor.

Generally, the county experienced improvements with respect to carbon monoxide pollution in the 1980s. At one monitoring site, the number of exceedances of the maximum eight-hour primary health standard for carbon monoxide fell from a high of 52 exceedances in 1982 to 10 exceedances in 1985. In order to continue to reduce levels of carbon monoxide pollution in the county, an automobile inspection/maintenance and anti-tampering program was implemented in 1986.

Particulate pollution levels in the county remained about the same from 1979–85. The 24-hour TSP standard of 260 $\mu g/m^3$ was exceeded as many as 10–18 times per year. The average annual geometric mean from 1979–85 for TSP at the Lindon monitor equalled 65 $\mu g/m^3$. This mean level of TSP exceeded EPA's annual secondary standard of 60 $\mu g/m^3$ but not the annual primary health standard of 75 $\mu g/m^3$. Monitoring of sulfur dioxides (SO_2) was conducted in the county in the 1970s but was discontinued because SO_2 levels were substantially below the annual primary health standard of .03 ppm, the 24-hour primary health standard of .14 ppm and the secondary 3-hour standard of .5 ppm.

The primary industrial source of fine particulate pollution as measured by PM_{10} in Utah County is the Geneva steel mill, commonly referred to as Geneva, located near Orem (Figure 1). When in operation, the mill emits approximately 82 per cent of all industrial sources of PM_{10} including power generation.[27] When all sources are accounted for, Geneva's contribution to PM_{10} equals 47 to 80 per cent of total emissions.[27] Other sources of PM_{10} include wood burning (approximately 16 per cent), road dust (approximately 11 per cent), diesel fuel and oil combustion (approximately 7 per cent). Also, Geneva's contribution to the county's industrial emissions of sulfur oxides, nitrogen oxides, hydrocarbons, and carbon monoxides are approximately 95, 98, 86, and 82 per cent, respectively.[27]

Geneva was built for the US Government in the early 1940s as part of the World War II effort. It was sold to US Steel Corp in 1946. On August 1, 1986, the Geneva steel mill shut down as a result of a labor dispute with USX Corporation (previously US Steel Corp.) The plant reopened on September 1, 1987 under a new owner, Basic Manufacturing and Technologies of Utah, Inc. In April 1985, the Bureau of Air Quality began to daily monitor PM_{10} at a site in Lindon (Figure 1) using a Sierra Anderson high volume sampler. During the winter season of 1985/86, Geneva was still open and 24-hour PM_{10} levels exceeded 150 $\mu g/m^3$ on 13 occasions. The highest single day concentration was 365 $\mu g/m^3$. During the winter of 1986/87 while Geneva was shut down, 24-hour PM_{10} levels never exceeded 150 $\mu g/m^3$. During the winter of 1987/88, following the reopening of Geneva, 24-hour PM_{10} levels exceeded 150 $\mu g/m^3$ on 10 occasions with a single day high at 223 (Figure 2).

During the winter of 1985/86, a random sample of county residents indicated that most residents thought that air quality was a serious problem and 29 per cent indicated that they had one or more members of their family who had health problems that were aggravated by air pollution.[28] During the winter of

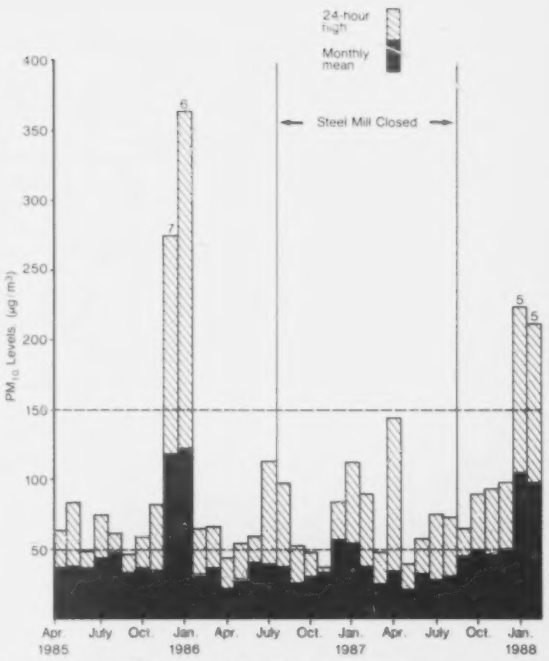

FIGURE 2—Monthly Mean and 24-Hour High PM_{10} (fine particulate pollution) Levels, Utah Valley, April 1985–January 1988

1987/88, following the closure and subsequent reopening of the steel mill, there was much local discussion about the contrast in air quality. The frequency and severity of respiratory illnesses were commonly perceived to have dropped when the mill was shut down, and then dramatically increased when it reopened. Newspaper articles, letters to the editor, and testimonials in public meetings often reflected this perception by many in the community.

Health Data

Hospital admissions data for respiratory-related illnesses were collected from April 1985 through February 1988. There were only four hospitals in the county. Data were collected from three of them that together had 579 beds. The other hospital in the County had only 20 beds, no pediatrics unit, no pulmonologist on its staff, and rarely provided inpatient care for respiratory illnesses.

A preliminary study of diagnosis-related groups (DRGs)[29] at Utah Valley Regional Medical Center indicated that DRGs 79, 80, and 81 (Respiratory Infections and Inflammations), DRGs 85 and 86 (Pleural Effusion), DRG 87 (Pulmonary Edema and Respiratory Failure), DRG 88 (Chronic Obstructive Pulmonary Disease), DRGs 92 and 93 (Interstitial Lung Disease), and DRGs 99 and 100 (Respiratory Signs and Symptoms) accounted for only 4.9, 0.6, 1.6, 3.3, 0.8, and 5.8 per cent of the collected cases, respectively. Initial comparative statistical analysis and regression analysis did not reveal any association between the closing and subsequent reopening of Geneva or PM_{10} levels and hospital admissions for any of these DRGs individually or collectively.

The bulk of the respiratory illness (83 per cent) were for the six DRGs that included 89, 90, and 91 (Simple Pneumonia and

Pleurisy) and 96, 97, and 98 (Bronchitis and Asthma) with 42 and 41 per cent of the cases, respectively. As a result, this analysis focuses on hospital admissions where the principal diagnosis was classified within one of these six DRGs.

Monthly admissions data for these six DRGs were compiled for each of the three hospitals. Records for outpatient and emergency admissions were not complete or consistent for the full time period. Therefore, only inpatient data were used in this analysis. Accurate records for Mountain View Hospital were available for the time periods April 1985 through September 1986 and January 1987 through February 1988. Accurate inpatient records for the other two hospitals were available from April 1985–February 1988.

Analysis Conducted

Utah Valley Regional Medical Center's admissions were sorted into in-county and out-of-county admissions. Both Utah Valley Regional Medical Center and American Fork Hospital are located within the central urban area of the county, near the major sources of pollution. The primary analysis used the combined Utah Valley Community Hospital in-county admissions and American Fork Hospital admissions as an indicator of the level of relatively severe respiratory illness in the urban area of the county.

Three other sets of hospital admissions data were used as control variables: "all-other" admissions from Utah Valley Regional Medical Center and American Fork Hospital, excluding in-county admissions for pneumonia, pleurisy, bronchitis and asthma; out-of-county admissions to Utah Valley Regional Medical Center for pneumonia, pleurisy, bronchitis, and asthma; and admissions to Mountain View Hospital in Payson for the same illnesses.

Hospital admission levels were compared across months with different levels of particulate pollution as measured by PM_{10}. Admission levels were also compared across comparable periods of time when the steel mill was open, closed, and then reopened. Finally, monthly hospital emissions were regressed on PM_{10} levels and weather variables obtained at Brigham Young University.[30]

Results

Comparative Analysis

As can be seen in Figure 2, there was considerable variability in PM_{10} levels in the county over the study period. During those months when exceedances of the 24-hour PM_{10} standard of 150 $\mu g/m^3$ occurred, the number of admissions for children, 0–17 years of age, was nearly triple the number of admissions for months with no exceedances (Table 1). In adults, admissions were approximately 44 per cent higher during the months when exceedances occurred.

During months when the arithmetic mean PM_{10} levels were equal to or greater than 50 $\mu g/m^3$, children admissions were nearly double than when the average PM_{10} levels were less than 50 $\mu g/m^3$. Adult admissions were increased by approximately 47 per cent.

The above comparisons were complicated by the fact that the months with especially high levels of particulate pollution were during the winter, and the reason for the high incidence of respiratory illness may be at least partly attributed to winter weather. The intermittent operation of the steel mill provided the opportunity to compare different winter seasons with marked differences in PM_{10} levels. Figure 2 demonstrates that when the steel mill was closed, PM_{10} levels were relatively low. One concern about making observations pertaining to these time periods is that the winter when the Geneva steel mill was closed may have had relatively good weather conditions and limited conditions of stagnant air. Weather data indicated that temperatures fell below zero on only two occasions throughout the study period, both in January of 1988 when they fell as low as $-1°$ and $-7°$. Snowfall during this time period for 1985/86, 1986/87, and 1987/88 totaled only 45.5, 33.5 and 27.5 inches, respectively.[30]

The National Weather Service computes an air stagnation or clearing index for valleys in Western Utah, including Utah Valley.[31] The index ranges from 0–1000 with lower values indicating more stagnant air. When the index is less than 200 pollution dispersal is "very poor" and weather conditions are such that air pollution potential is high. The month with the lowest average clearing index occurred during the winter the mill was closed. The average clearing index for the winter period of December–February for 1985/86, 1986/87, and 1987/88 was 388, 345, and 367, respectively, and the number of days when the index was below 200 for the same time periods equalled 47, 54, and 47, respectively.[32] Based on this index the air was relatively more stagnant and had higher air pollution potential during the winter when the mill was shut down than the previous or following winters.

Table 2 presents comparisons of hospital admissions be-

tween fall and winter periods when the steel mill was open, closed, and reopened. During the winter months from December to February, hospital admissions for children were approximately three times as high when the steel mill was open than when it was closed. Even during the Fall months (September–November) when no exceedances for the 24-hour primary health standard occurred, children admissions for bronchitis and asthma were approximately twice as high when the steel mill was open. Adult hospital admissions were not as obviously associated with the reductions of PM_{10} that accompanied the closure of the steel mill. There was, however, a notable increase in adult admissions following the reopening of the mill.

Regression Analysis

The results of some of the regression models are presented in Table 3. Model 1 regresses total monthly hospital admissions for pneumonia, pleurisy, bronchitis, and asthma on current and lagged PM_{10} levels. All lagged variables simply refer to the previous month's value. The results demonstrate a strong correlation between admissions and PM_{10}. In fact, 59 per cent of the variance in monthly admissions for these respiratory illnesses is explained by current and lagged monthly mean PM_{10} levels alone.

In Model 2, current and lagged mean low temperature variables were also included. This relatively simple linear model with only PM_{10} and temperature variables explains 83 per cent of the variance in total hospital admissions for these respiratory illnesses. The correlation between mean PM_{10} levels, mean low temperatures and hospital admissions is particularly striking when actual admissions and estimated admissions based on Model 2 are plotted together over time (Figure 3). Models 3–14 repeat the analysis done in Models 1 and 2 for total adult admissions, total children admissions, adult admissions for pneumonia and pleurisy, children admissions for pneumonia and pleurisy, adult admissions for bronchitis and asthma, and children admissions for bronchitis and asthma.

Autocorrelated errors exist with some of the models, particularly those with only PM_{10} levels as independent variables. This autocorrelation, however, is largely eliminated when weather variables are included. For example, the Durbin-Watson D statistic is 1.0 for Model 1 and 1.6 for Model 2. It is 1.3 for Model 3 and 2.0 for Model 4. There is also collinearity between PM_{10} levels and temperature. The correlation coefficient between the mean low temperature and monthly mean PM_{10} levels equals −0.32. This collinearity complicates the analysis and makes specific best point estimators of the correlation coefficients difficult to estimate. However, Model 2 was reestimated using a nonlinear quasi-Newton iterative procedure which gave identical regression coefficients with somewhat smaller standard-errors.

Numerous other regression models were estimated that included snowfall, rainfall, evaporation, monthly mean temperatures, and mean high temperatures. The weather variable that was consistently most highly correlated with admissions was the mean low temperature. Regressions that used PM_{10} levels lagged for two months, and dummy variables that indicated the opening and closing of the steel mill and inversion seasons were also tried. Even with the inclusion of these other variables, strong, positive, correlations between hospital admissions and PM_{10} levels remained. Regression models were also estimated with monthly 24-hour high PM_{10} levels used as independent variables. The results were similar to those in Models 1–14 as presented in Table 3, but 24-hour high PM_{10} levels were generally not as strongly correlated with admissions as were the mean PM_{10} values.*

Analysis with Control Variables

Neither comparative analysis nor regression analysis revealed any associations between the control variables and PM_{10} levels or the closing and reopening of the steel mill. "All-other" admissions that excluded in-county admissions for pneumonia, pleurisy, bronchitis, and asthma averaged 1,562 per month and appeared to be declining slightly over the study period. No seasonal variability nor any association with PM_{10} levels or the closing and reopening of the mill was observed. Monthly "all-other" admissions regressed on PM_{10} levels and temperature variables (Models 15 and 16 in Table 3) showed no significant correlation with PM_{10} levels.

Out-of-county hospital admissions to Utah Valley Regional Medical Center and admissions to Mountain View Hospital in Payson were regressed on PM_{10} levels and temperature variables. Models 17 and 18 in Table 3 present the results of the regressions for total out-of-county admissions for pneumonia, pleurisy, bronchitis, and asthma. The same regressions were also run on out-of-county and Mountain View Hospital with admissions broken down by adults, children, and respiratory illnesses, as done in Models 1–14.

Although Payson is located in the county and should be similarly influenced by contagious illness, it is over 32 kilometers from the major sources of pollution and should not be as influenced by monitored levels of PM_{10}.

The regressions using out-of-county and Mountain View Hospital admissions are limited by the fact that only about 15 per cent of Utah Valley Regional Medical Center admissions are out-of-county, and Mountain View Hospital's data are missing for the months of October, November, and December of 1986. The results indicated that there was significant correlation between the mean low temperature lagged variable similar to those in the earlier regressions. There was no positive correlation between out-of-county or Mountain View Hospital admissions and PM_{10} levels, however.

Discussion

The results indicated that hospital admissions for respiratory illnesses were strongly associated with PM_{10} levels. This association is much stronger for children than adults, and somewhat stronger for bronchitis and asthma than for pneumonia and pleurisy. These associations were particularly strong with monthly lagged variables suggesting that the health effects of particulate pollution are cumulative and that it takes time before they are manifested in inpatient hospital admissions data.

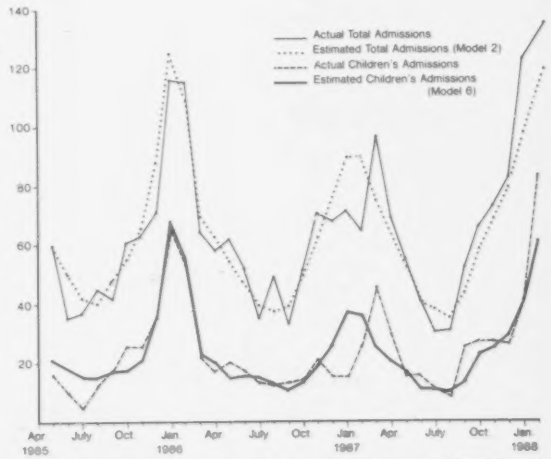

FIGURE 3—Actual and Estimated Hospital Admissions, April 1985 through January 1988, Utah Valley

Also, increased admissions for children are observed even for months when PM_{10} did not exceed 150 $\mu g/m^3$, suggesting that this standard may not be adequate protection for some children.

There are several concerns about these observations. One concern is that if increases in contagious illnesses such as influenza by chance coincided with periods of high PM_{10} levels, particularly during the winters when the steel mill was open, then the observed correlation between PM_{10} and admissions may be spurious. It would be expected, however, that if this were the case, the same correlation would be found in hospital admissions from neighboring counties or communities unaffected by Utah Valley's principal sources of pollution. No such correlation was found for out-of-county admissions to Utah Valley Regional Medical Center or to Mountain View Hospital in nearby Payson. Nor was such correlation found between PM_{10} levels and non-respiratory hospital admissions.

Another concern is that often levels of several air pollutants rise and fall in concert. PM_{10} may be a surrogate for other air pollutants with which it is temporarily associated. Two pollutants that may have had similar impacts on respiratory illnesses during the study period are total suspended particulates and ozone. Because PM_{10} measures only relatively small particles of particulate pollution, and because it is the smaller particles that are expected to pose the greatest health risks, it is considered the most appropriate measure of particulate pollution as it relates to respiratory health.[1] Regression models estimated with monthly mean total suspended particulate levels used as independent variables yielded results similar to Models 1–14 presented in Table 3 which used PM_{10}. The correlations between admissions and total suspended particulates were generally not as strong as those between admissions and PM_{10}.

There was no evidence that suggested that PM_{10} was serving as a surrogate for ozone pollution. The only times ozone pollution in Utah Valley rose to levels of any consequence was in the summer months during hot sunny days, whereas the periods of high levels of PM_{10} and hospital admissions for respiratory illness occurred mostly during the winter months when the steel mill was in operation. The results of this study suggest that the dominant pollution in terms of its impact on respiratory health in Utah Valley is particulate pollution and that PM_{10} is a better indicator than TSP.

Finally, the association between respiratory illness and particulate pollution found in this study is relatively large as compared with some previous studies.[20–22,33] This relatively strong association can be explained in part because PM_{10} is a better indicator of particulate pollution as it relates to respiratory health than previously used indicators.[1] Also, because Utah Valley experiences relatively high levels of particulate pollution, yet has an extremely low portion of its population that smoke, particulate pollution is likely a relatively large contributor to respiratory disease in the county.

ACKNOWLEDGMENTS

Special thanks are given to Victor Archer, MD, Clark Bishop, MD, Don Bloxham, PhD, Joseph Miner, MD, and Henry Yeates, MD, as well as personnel at the Utah Bureau of Air Quality; Utah Valley Regional Medical Center; American Fork Hospital; and Mountain View Hospital for providing information, data, helpful suggestions, and reviews of earlier drafts of this manuscript.

Exposure to Occupational Hazards among Hispanics, Blacks, and Non-Hispanic Whites in California

James C. Robinson, PhD, MPH

Abstract: Relative risks of exposure to each of six types of occupational injuries and illnesses for Hispanic and Black workers compared to Whites who are not Hispanic were calculated using 1986 California data. Among males, Hispanics faced relative risks of exposure to all hazards adjusted for education and years of work experience of 1.33 (95% CI 1.22, 1.45), while Blacks faced relative risks of 1.17 (1.0, 1.37). Among females, adjusted relative risks were 1.19 (1.09, 1.29) for Hispanics and 1.31 (1.15, 1.50) for Blacks. (*Am J Public Health* 1989; 79:629–630.)

Introduction

Several studies have documented racial differences in exposure to occupational hazards, using national data on working conditions faced by Black and White workers.[1–4] These studies have been forced by the nature of the data they used to group Hispanics together with Whites who are not Hispanic. This approach not only conceals relative exposure differences between Hispanic and other Whites, it also may underestimate the difference in exposure levels between Blacks and Whites. The present study examined 1986 data on exposure to occupational injury and illness hazards for 5,737 workers in California, and calculated relative risks of exposure for Hispanics and Blacks, respectively, compared to Whites who are not Hispanic.

Methods

Information on work-related injuries and illnesses in California was obtained for 1986 from the mandatory reporting system of the state Workers' Compensation system. Under California law, employers must report to the state any work-related injury or illness that causes absence from work lasting one or more full days. These incidence reports are not directly influenced by whether or not the injuries and illnesses subsequently result in a compensation claim. The California Department of Industrial Relations tabulates these reports by occupation, industry, type of injury or illness, and a number of other criteria.[5]

Data were obtained for each of the five major types of injury and for acute illnesses as well as for total injuries and illnesses for each three digit Census occupation classification. Frequencies were converted to rates per 1,000 workers per year using occupation-specific California employment data from the 1980 Census of Population,[6] inflated by the 1980–86 rate of growth in total California employment.

The five major classifications of occupational injuries, which in 1986 accounted for 78.4 per cent of all reported injuries and illnesses, were: strains, sprains, dislocations, and hernias (43.3 per cent); cuts, lacerations, and punctures (13.4 per cent); fractures (10.0 per cent); crushing injuries, contusions, and bruises (8.0 per cent); and abrasions and scratches (3.7 per cent). Acute illnesses accounted for 7.5 per cent of all events.

Demographic data were obtained from the March 1986 Current Population Survey (CPS) of the US Department of Commerce's Bureau of the Census.[7] The March 1986 survey contained data on 6,175 employed Californians, 5,737 of whom were employed in occupations for which injury and illness data were available. Of 2,649 female workers, 676 were Hispanics, 1,798 other Whites and 175 Blacks. Of 3,088 male workers, 968 were Hispanic, 1,966 other Whites and 154 Black.

Educational attainment as recorded by CPS was categorized as: not graduated from high school, high school graduates, less than four years of college, and four or more years of college. A potential work experience measure was constructed by subtracting years of education plus five from years of age.[8] The square of this measure was also employed, in order to capture any nonlinear association between work experience and labor market rewards.

The occupational injury and illness rates were matched with the demographic data using three digit Census occupation codes. Each individual worker was thus ascribed the level of risk for each type of injury and for acute illness that was the average for his or her three digit occupation.

Injury rates were first transformed into logarithmic units and regressed on dichotomous variables indicating Hispanic and Black ethnicity, respectively, with other Whites who were not Hispanic composing the comparison category. Relative risks were calculated by taking the exponent of the coefficients on the ethnicity variables. Relative risks were adjusted by taking the exponent of the coefficients on the ethnicity variables in multivariate regressions that controlled for the four education and two work experience variables. The injury and illness rates were approximately lognormally distributed.

Results

Among men, Hispanics faced unadjusted relative risks for all injuries and illnesses combined of 2.21 (95% confidence interval = 2.04, 2.40), compared to other Whites; Blacks

TABLE 1—Relative Risks of Exposure for Male Workers, Adjusted for Levels of Education and Potential Work Experience

Injuries/Illness	Hispanics (95% CI)	Blacks (95% CI)
All Injuries and Illnesses	1.33 (1.22, 1.45)	1.17 (1.00, 1.37)
Sprains and Strains	1.33 (1.22, 1.45)	1.22 (1.04, 1.44)
Cuts and Punctures	1.42 (1.27, 1.57)	1.03 (0.85, 1.26)
Fractures	1.27 (1.16, 1.38)	1.05 (0.89, 1.23)
Crushing Injuries and Contusions	1.42 (1.29, 1.56)	1.24 (1.04, 1.48)
Abrasions	1.48 (1.32, 1.66)	1.03 (0.83, 1.28)
Acute Illness	1.25 (1.16, 1.34)	1.19 (1.04, 1.36)

TABLE 2—Relative Risks of Exposure for Female Workers, Adjusted for Levels of Education and Potential Work Experience

Injuries/Illness	Hispanics (95% CI)	Blacks (95% CI)
All Injuries and Illnesses	1.19 (1.09, 1.29)	1.31 (1.15, 1.50)
Sprains and Strains	1.18 (1.08, 1.30)	1.40 (1.22, 1.62)
Cuts and Punctures	1.26 (1.13, 1.40)	1.12 (0.95, 1.33)
Fractures	1.11 (1.03, 1.19)	1.22 (1.08, 1.37)
Crushing Injuries and Contusions	1.24 (1.13, 1.36)	1.32 (1.14, 1.53)
Abrasions	1.30 (1.17, 1.44)	1.30 (1.11, 1.53)
Acute Illness	1.15 (1.07, 1.23)	1.30 (1.17, 1.45)

faced relative risks of 1.41 (95% CI = 1.18, 1.69). Hispanic men had unadjusted relative risks greater than those of Blacks in each individual category of injury and illness. Hispanic women faced relative risks of exposure to all occupational hazards of 1.49 (95% CI = 1.38, 1.62), while Black women faced relative risks of 1.31 (95% CI = 1.14, 1.50).

Tables 1 and 2 present relative exposure risks for Hispanics and Blacks compared to other Whites who were not Hispanic after controlling for educational level and potential work experience. The size of the relative exposure risks are reduced, but substantial ethnic differences remain. Among Hispanic workers, the relative risk for all exposures declined from 2.21 to 1.33 for males and from 1.49 to 1.19 for females. The relative risk for all exposures declined from 1.41 to 1.17 for male Black workers, but for female Blacks were almost identical to their unadjusted relative risks.

Discussion

Hispanic and Black workers in California are exposed to higher risks of occupational injury and acute illness than are other White workers who are not Hispanic, even after controlling for years of education and potential work experience. These ethnic differences may be associated with differing job characteristics. Hazardous occupations have been found to offer fewer rewards and amenities in most dimensions than non-hazardous occupations, including fewer opportunities for worker control over the pace and content of the work process; fewer possibilities for on-the-job training and promotion[9]; higher rates of temporary and permanent layoffs[10]; and lower wages.[9,11]

The limitations of these findings should be stressed. No data sources currently exist that include information on health and safety hazards in particular jobs and on the ethnic and socioeconomic characteristics of the workers employed in them. This study combined three different data sets: injuries and illnesses from state Workers' Compensation records, employment data from the Census of Population, and demographic and socioeconomic data from a large survey of individuals. The limitations are especially serious with respect to occupational illnesses as distinct from injuries, since Workers' Compensation programs are mainly focused on acute illnesses rather than diseases with long latency periods. Efforts to improve the quality of data on occupational illness and injury for surveillance purposes should include ethnic and socioeconomic information wherever possible.

Lead Toxicity and Iron Deficiency in Utah Migrant Children

Stephen D. Ratcliffe, MD, MSPH, Jeffrey Lee, MPH, PhD, Lawrence J. Lutz, MD, MSPH, F. Ross Woolley, PhD, Sandra Baxter, MD, Fred Civish, MD, and Mark Johnson, MD

Abstract: We determined the frequency of presumptive iron deficiency and lead toxicity in 198 Utah migrant children, ages 9–72 months, during the summer of 1985. There were no confirmed cases of lead toxicity. Thirteen per cent of those tested and 30 per cent of the children ages 9–23 months were iron deficient. Hematocrit determinations accurately predicted iron deficiency in only 35 per cent of the children confirmed to have this disorder via erythrocyte protoporphyrin screening. (*Am J Public Health* 1989; 79:631–633.)

Introduction

Lead toxicity and iron deficiency have their highest prevalence among children of low socioeconomic status.[1] Their hematologic and nonhematologic manifestations reflect impaired enzymatic and metabolic processes. Both conditions impair normal growth and development in children.[2–14]

The Centers for Disease Control (CDC) recently lowered the toxicity standards in children from a blood lead level of 1.45 μmol/L to 1.21 μmol/L.[15]

In some ethnic groups,the use of folk remedies has led to unintentional lead poisoning of children.[16] Sixteen cases of lead poisoning in Mexican American children due to the use of greta or azarcon were reported between 1981 and 1985.[17,18] This folk remedy is a fine powder whose content is 70 to 90 per cent inorganic lead and whose estimated lifetime usage among Mexican Americans in the American southwest is 10 per cent.[19]

Of the migrant children in Utah, approximately 80 per cent are Mexican American whose home base is either Mexico or the lower Rio Grande Valley in Texas.* The migrant children in Utah are representative of the population thought to be at risk for lead toxicity related to folk remedy ingestion.

The screening test used in our study, erythrocyte protoporphyrin (EP), enabled us to determine the frequency of both lead toxicity and iron deficiency in the children evaluated.[20–23]

Methods

During the summer of 1985, 334 migrant children were enrolled in seven Head Start centers in Utah. Of these children, 269 were in the targeted age range of 9–72 months.[24] We tested 198 children (73.8 per cent of those eligible) for lead toxicity and iron deficiency after obtaining informed consent from their parents.

Three medical students performed the screening tests for lead toxicity and iron deficiency. They adhered to the protocol for micro blood sampling that was published by the CDC's Blood Lead Proficiency Testing Program.[25]

The EP and hematocrit samples were collected in 100 μl heparinized capillary tubes. Within two to six hours of the sampling, the hematocrit determinations were made using a Clay Adam's Triac Centrifuge (Model #0200). The EP tests were made with a front-faced hematofluorometer (ESA Zinc Protoporphyrin), which underwent factory standardization at the start of the study and was calibrated daily with control samples.

At the time of the capillary sampling, an additional two 100 μl lead-free (ESA) capillary tubes were collected from each subject for blood lead determinations. Blood lead analyses were performed at a CDC accredited laboratory using anodic stripping voltammetry (ESA Model 3010A). The precision of the testing method was confirmed by running dual capillary samples for blood lead determinations for the first 90 migrant children screened. The Pearson correlation (r) was 0.94 for these paired samples.

Children having EP levels less than 0.62 μmol/L were not tested further. If the EP were greater than .62 μmol/L and the lead level were less than 1.21 μmol/L, iron deficiency would be diagnosed according to the guidelines established by Yip in 1983.[26] These guidelines have a sensitivity of 88 per cent, a specificity of 90 per cent, and a positive predictive value of 38 per cent based on a population prevalence of 6.6 per cent.

Children with both elevated EP (≥.62 μmol/L) and lead (≥1.21 μmol/L) levels underwent venipuncture to confirm the elevated lead level. If confirmed, a diagnosis of lead toxicity would be made according to CDC standards.[27] Iron and total iron binding concentration levels (TIBC) were then run. An iron-to-TIBC ratio of 0.12 or less would confirm the concurrent diagnosis of iron deficiency.[28]

This study protocol was approved by the Institutional Review Board at the University of Utah.

Results

Table 1 summarizes the age, racial, and gender distribution of the migrant children screened. There were no confirmed cases of lead toxicity, and no cases of lead contamination in the capillary tube samples sent for analyses. Table 2 summarizes the frequency of iron deficiency according to age and racial categories. Of the 198 migrant children tested, 26 (13.1 per cent) were iron deficient according to our protocol; 29.7 per cent of the children ages 9–23 months were iron deficient compared to 13.5 per cent and 3.1 per cent of the children ages 24–47 months and 48–71 months.

TABLE 1—Age, Sex, and Racial Distribution of Children Screened

Characteristics	% Migrant (N:198)
Age	
9–23 months	18.7
24–47 months	48.5
48–71 months	32.8
Sex	
Male	44.9
Female	55.1
Race	
Caucasian	2.5
Mexican American	75.3
Native American Kickapoo	12.6
Native American Navajo	9.6

TABLE 2—Percentage of Migrant Children Iron Deficient According to Race and Age

Race	% 9–23 Months	% 24–47 Months	% 48–71 Months	Total
Hispanic	22.7% (22)	16.4 (73)	1.9 (54)	12.1 (149)
Native American Kickapoo	55.6 (9)	7.7 (13)	0.0 (3)	24.0 (25)
Native American Navajo	20.0 (5)	0.0 (8)	16.6 (6)	10.5 (19)
Caucasian	0.0 (1)	0.0 (2)	0.0 (2)	0.0 (5)
Total	29.7 (37)	13.5 (96)	3.1 (65)	

NOTE: Number screened is shown in parenthesis.

Hematocrit determinations were not strongly predictive of iron deficiency. Of 37 children age nine months to two years, only four had hematocrits less than 35 per cent, while 11 of the 37 were iron deficient based upon EP criteria.

Discussion

No cases of lead toxicity were confirmed in the population we studied. Although the study adhered to lead toxicity standards established by the CDC, this screening method has a sensitivity of only 50 per cent in detecting blood lead levels greater than 25 μg/dl.[30] Thus, it is possible that a few elevated blood lead levels may have been missed. Moreover, a recent statement on childhood lead poisoning by the American Academy of Pediatrics suggests that evidence is mounting to lower the level of blood lead which would be considered elevated.[31,32]

We have demonstrated that capillary sampling for lead determinations can be carried out for large numbers of children in remote settings with no breakage or contamination of specimens. This sampling technique was well tolerated by the children.

Iron deficiency was common among these migrant children, especially in the nine months to two year age group. This is the time period when the growth and development of children are most sensitive to the adverse effects of iron deficiency.[11–19] Migrant children should be included with other groups that have high prevalence of iron deficiency (urban Blacks, Indochinese refugees, and other low socioeconomic groups).[33,34]

We have shown, as have others, that the hematocrit determination is an insensitive screen for iron deficiency.**,[34] The office-based clinician generally has only this test available; thus, the problem of undetected iron deficiency remains a real one. The use of the EP as a screening test for iron deficiency seems warranted, particularly for those practitioners serving high-risk populations.

The Relationship of Park Maintenance and Accessibility to Dogs to the Presence of *Toxocara* spp. Ova in the Soil

KAREN E. LUDLAM, BS, AND THOMAS R. PLATT, PHD

Abstract: Three parks in St. Joseph/Benton Harbor, Michigan were examined for the presence of *Toxocara* spp. ova in the soil. Nineteen per cent (22/114) of the samples contained ova, and mean density (eggs/5 g soil) was 0.73. The density of two samples, collected at the base of playground equipment in one park, was >2.1, which is considered sufficient for human infection. Subjective assessments of park maintenance and accessibility to dogs were not good indicators of the presence of *Toxocara* spp. ova. (*Am J Public Health* 1989; 79:633–634.)

Introduction

Visceral larva migrans (VLM) is a disease caused by the migration of the larval nematodes, normally parasitic in animals other than humans, through the extraintestinal tissues of humans.[1] *Toxocara canis*, the common roundworm of dogs, is regarded as the primary agent of this disease. Risk of human infection is greatest in young children, and most likely to occur via ingestion of embryonated eggs in the soil rather than through direct contact with an infected animal.[1]

The purpose of this study was to survey three parks in the St. Joseph/Benton Harbor area of southwestern Michigan for the presence of *Toxocara* spp. ova in the soil. Selection was based on subjectively determined differences in accessibility and levels of maintenance.

Methods

Study Sites

Milton Park, a well-kept neighborhood park used by children and adults, is located in an older neighborhood with some commercial development. It is approximately 70 m × 75 m, and is regularly maintained. There are conspicuous "No Dogs Allowed" signs posted around the park border.

Napier Park, a small triangular play area, approximately 45 m on a side, is located in a middle-class suburban neighborhood, frequently used by neighborhood children. Regular maintenance appears minimal, and there are no signs restricting access by dogs.

Corronde Park, the largest of the three, is bordered on one side by the St. Joseph River and regularly maintained. Facilities include: tennis courts, a baseball field, and picnic pavilions. It is isolated from surrounding housing and is typically used for picnics and family gatherings. Dogs are permitted but must be on a leash or chained. Soil samples were collected in a large play area (100 m × 55 m) adjacent to the river.

Soil Collection

Samples were collected at 9 m intervals, along transect lines approximately 9 m apart. Composite soil samples, totaling 40 g, were taken to a depth of 1–2 cm. Five to six plugs of soil were taken with a soil corer within a one square foot area at each grid point. Additional samples were collected at the bottoms of slides, bases of teeter-totters, and underneath swings. Samples were not collected when grid points fell on sidewalks or other obstructions.

Laboratory Procedures

Collection of eggs followed Method 6 of Kazacos[2] with minor variations, using 20 gram subsamples from each site. The specific gravity of the $NaNO_3$ used in the final flotation was 1.30 (Kazacos, personal communication). No attempt was made to differentiate between eggs of *Toxocara canis* and *T. cati*.

Results

Nineteen per cent (22/114) of the samples examined were positive for *Toxocara* spp. ova (Table 1). No ova were found in Milton Park, while Napier and Corronde Parks had similar prevalences of approximately 30 per cent. Mean density (ova/5g of soil) is higher in Corronde, but mean density for Napier falls within the 95% confidence limits of the differences between the two parks.

The five transects at Corronde Park fell into two distinct groups (Table 2). Two transects nearest the river (A & B) had only one positive sample between them. The remaining transects (C, D, and E) passed through the general play area, with prevalences between 50 and 60 per cent.

TABLE 1—Results of the Examination of Soil Samples for *Toxocara* spp. Ova from Parks in St. Joseph/Benton Harbor, Michigan

Parks	No. Samples	No. Positive	% Prevalence	Mean Density (range)
Milton	48	0	0	0
Napier	13	4	31	0.25
Corronde	53	18	34	0.83* (0.25,5.5)
Total	114	22	19	0.73 (0.25,5.5)

*Approximate 95% confidence interval for Corronde-Napier Parks is 0.08, 1.08.

TABLE 2—Presence of *Toxocara* spp. Ova from five Transects* in Corronde Park

Transect	A	B	C	D	E
Ova present	0	1	6	5	5**
Ova absent	10	9	4	5	5

*Ten samples collected from each transect.
**Approximate 95% confidence interval for $Transect_{C,D,E}$–$Transect_{A,B}$ (48 per cent) is 26–68 per cent.

Discussion

Overall prevalence of *Toxocara* spp. ova from soil samples in this study (19 per cent) falls in the mid-range of other studies of public parks and playgrounds in North America.[3–6] Reasons for variation include, but are not restricted to, environmental conditions, choice of sampling sites, the utilization of the area by dogs and cats, and the prevalence of infection of *Toxocara* spp. in animals in the area.[7]

Subjective assessment of maintenance and access was of little value as a predictor of contamination. No ova were found in Milton Park, which is well maintained and has conspicuous signs prohibiting dogs. Napier and Corronde Parks differ markedly in appearance, maintenance, and accessibility, therefore, the similarity in prevalence (Table 1) must be based on the type of utilization. The majority of dogs in Corronde Park are brought by their owners, but must be leashed or chained. Visits are likely to be prolonged, resulting in a high probability that the animal will defecate on the premises. Napier Park, on the other hand, is more likely to be visited for shorter durations, e.g., by strays or pet owners taking animals there specifically for the purpose of defecation, rather than allowing the animal to defecate on private property and risk confrontation with the owner or resident.

Prevalence of *Toxocara* spp. ova is unquestionably a factor of how a park is actually used by pet owners rather than simply the accessibility of the area to animals. The primary factor is human behavior and not the behavior of the dog: strays would hardly be deterred by the presence of signs. Despite the fact that Napier Park appeared to have a lower level of maintenance and is more accessible to strays than Corronde Park, the mean density of ova was higher in Corronde.

The prevalence of eggs was higher in the three transects which pass through the general play area in Corronde Park than in the two transects immediately adjacent to the river. Two positive samples from Transect C (at the base of a large, jungle gym complex) had densities of 3.4 and 5.5/5 g of soil. These densities are above the level (2.1 ova/5g) considered sufficient to result in human infection,[8] although justification for this threshold value is obscure.

The numbers of eggs found in the present study were generally low, but this does not mean there is no cause for concern. If eggs are concentrated in areas where children play, the probability of infection is real even if the average for the park falls below the values considered necessary for human infection.

American Indian Youth and Drugs, 1976–87: A Continuing Problem

FRED BEAUVAIS, PHD, E.R. OETTING, PHD, WILLIAM WOLF, MPA, AND RUTH W. EDWARDS, MBA

Abstract: Continuing surveillance of drug use among American Indian adolescents living on reservations shows them to have rates of use higher than those of their non-Indian counterparts. Marijuana use is particularly high among Indian students. By the 7th grade a significant number of Indian youth have tried drugs, particularly marijuana and alcohol, and there are few significant differences by gender. Based on observed patterns of use, intervention strategies need to begin in the elementary school years and target both males and females equally. (*Am J Public Health* 1989;79:634–636.)

Introduction

We have been collecting data on drug use rates among American Indian youth since 1975.[1–3] In addition to monitoring levels of use, we have conducted a series of studies examining the etiology of drug and alcohol use in this population.[4,5] In general, findings to date have shown that Indian youth have higher rates of drug use than non-Indian youth for nearly all drugs, and the interactions within small groups of peers (what we refer to as "peer clusters") have the strongest influence on a youth's decision to use or not use drugs. The latter finding is consistent with what we have

found for non-Indian youth.[6] There is no clear explanation for the higher rates of use for Indian youth although one can speculate that conditions of poverty, prejudice, and lack of opportunity found in many Indian communities create social conditions that encourage substance use. Liban and Smart, for example, found that Indian and non-Indian youth had similar rates of drug use when controlling for socioeconomic status.[7]

This article will update the previous data on trends in drug use of Indian youth who live on reservations.

Method

Instrument

The data are collected through self-administered, anonymous questionnaires given to students during a regular school period by the classroom teacher. The instrument has been developed specifically for use with Indian youth, and numerous revisions based on administration to over 30,000 Indian adolescents have led to a highly reliable and valid survey.*

Sample

A probability sample among Indian youth is extremely difficult to establish. Populations are remote, scattered, highly mobile, and often ill defined. As an alternative, reservations are classified on several demographic dimensions and an annual sample is constructed to represent the range on those dimensions. The parameters considered in selection include reservation size, geographic location, degree of isolation, and cultural diversity. The latter dimension is difficult to define since there are over 400 distinct tribes in the United States. There are cultural clusters, however, that may include many tribes with similar traditions, language, and history. The sampling plan draws from different clusters in any given year. Five to six tribes are selected each year yielding a sample of 1,000 to 2,000 youth.

The results are aggregated into biennial reporting periods which reduces any sampling bias that may occur in the annual selection procedure. Once a tribe is selected the survey is administered to every youth in the tribe who is attending school. The exception is in the large tribes where a sample of schools is used. Absentees and dropouts are not included.

The data collection methodology has remained consistent since 1975 assuring comparability across years.

Results and Discussion

Lifetime Prevalence: 7th–12th Grades

The most general measure of drug use is "lifetime prevalence," the question "Have you *ever* used?" (Table 1). While this does not provide information on amount or intensity of current use, it does yield an indication of the level of exposure to a drug in a population. If lifetime prevalence is high, the drug is clearly available and accessible.

The more commonly used drugs (alcohol, marijuana, and inhalants) increased in use quite sharply between 1975 and 1981. A similar pattern is seen for many of the other drugs. The interval from 1981 and 1985 was one of a general decline in lifetime prevalence for the most commonly used drugs. Marijuana use is illustrative, with a decrease from 74 per cent to 57 per cent. Inspection of the last two reporting periods suggests no further decline. Despite a slight rise for some drugs in 1988, it is premature to interpret this as the beginning of another period of increase.

The pattern showing a rapid increase in use of the most commonly used drugs through about 1981 and a modest decline after that is shared by both Indian and non-Indian youth.[8] This would suggest that young people of both races are responding similarly to the broad scale societal forces that influence drug use.

Gender and Age

The best available data for non-Indian youth show higher prevalence rates of both lifetime and last 30 days drug use for males for nearly all drugs.[9] When the Indian data are examined, however, females use drugs at the same rate as males. The exceptions are lower lifetime prevalence rates for females for cocaine (6.1 vs per 9.8 per cent) and smokeless tobacco (45.8 vs 71.4 per cent) and higher rates for cigarettes (82.0 vs 74.6 per cent). It is evident that interventions must target both sexes equally.

A significant amount of drug use occurs among Indian 7th graders, indicating that prevention must begin in the

[a]National High School Senior Survey[9]

elementary school years. For example, by the time they are in the 7th grade, 28 per cent of Indian youth report at least one episode of getting drunk, 44 per cent have tried marijuana, 22 per cent inhalants, 12 per cent stimulants, and 72 per cent cigarettes.

Comparison with Non-Indian Youth

Table 2 shows the 1986–87 comparison between Indian and non-Indian high school seniors[9] for lifetime and last 30 days prevalence. The Indian seniors have higher rates for six drugs but lower rates for only one drug—cocaine. Note in particular that on both prevalence measures, Indian students are showing considerably higher rates of marijuana use.

Since very high dropout rates have been reported for Indian students, it is likely that the rates reported for them in Table 2 would be even more elevated if all potential high school seniors were surveyed.[10]

Family Physicians' Views of Chiropractors: Hostile or Hospitable?

DAN CHERKIN, PHD, FREDERICK A. MACCORNACK, PHD, AND ALFRED O. BERG, MD, MPH

Abstract: Family physicians in the State of Washington were surveyed about their knowledge and views about chiropractors; 79 per cent (476) responded. Sixty-six per cent indicated discomfort with what they believed chiropractors do while acknowledging their effectiveness for some patients; 25 per cent viewed chiropractors as an excellent source of care for some musculoskeletal problems and only 3 per cent dismissed chiropractors as quacks that patients should avoid; 57 per cent admitted having encouraged patients to see a chiropractor. These views are less negative than those of organized medicine. (*Am J Public Health* 1989; 79:636–637.)

Introduction

Chiropractic began 100 years ago when its founder, a grocer and "magnetic healer," discovered what he believed to be the universal cause of all disease (vertebral subluxations) and its cure (spinal manipulation). After a shaky start, chiropractic is now recognized in all 50 states and is reimbursed under Medicare, Medicaid and by private insurers.[1]

The American Medical Association (AMA) has denounced chiropractic as "quackery and cultism" for decades, and in 1965 declared it unethical for physicians to have any professional association with chiropractors. Organized medicine's hostility toward chiropractic has left the public and many physicians[2] with the impression that physicians in general believe that chiropractors are quacks. This study describes practicing physicians' actual views of chiropractors.

Methods

All 181 family physicians employed by Group Health Cooperative of Puget Sound (GHC) and a 50 per cent random sample of the 847 non-GHC members of the Washington Academy of Family Physicians were surveyed about their management of low back pain. Approximately 75 per cent of family physicians in Washington are members of the

Increasing Response Rates in Physicians' Mail Surveys: An Experimental Study

BRIGITTE MAHEUX, MD, PHD, CLAUDINE LEGAULT, MSC, AND JEAN LAMBERT, PHD

Abstract: It is becoming increasingly difficult to obtain high response rates in physicians' mail surveys. In 1983–84, we tested the effectiveness of two techniques among 604 Quebec physicians who had not responded to an initial letter. A handwritten thank you note at the bottom of the letter accompanying the questionnaire and a more personalized mailout package increased response rates by 40.7 per cent and 53.1 per cent, respectively, compared to control groups. (*Am J Public Health* 1989; 79:638–639.)

Introduction

Epidemiologists, health administrators, and other public health professionals often rely on mailed questionnaires to obtain data from physicians. Mailed questionnaires cost less than interviews, are more convenient for the physicians, and allow less socially desirable responses.[1–4] The major disadvantage is the low response rate with the attendant problem of non-response bias.[5–7]

Many variables have been shown to influence physician response to mailed surveys. These variables include questionnaire length and format,[8–9] postage,[9] characteristics of investigator,[10] follow-up mailings,[11] and rewards.[12] In the study reported here, we experimentally tested the effectiveness of two relatively inexpensive procedures on physicians' response rates to a follow-up letter: 1) a handwritten postscriptum on the cover letter thanking the physician personally for participating in the study; and 2) a more personalized mailout package. Because of the small amount of time physicians have to answer the huge volume of mail they receive, we hypothesized that the two techniques would be more likely to catch physicians' interest and result in better response rates.

Methods

The experiment was conducted during a 1983–84 mail survey of a stratified sample of Quebec physicians (729 general practitioners and 379 specialists) aimed at determining the level of physicians' support for a number of patient care issues. The 70-item closed-ended questionnaire took about 20 minutes to complete. The data collection took place over six months and included four mailings, two of which served for the experimental study reported here.

At the first mailing, all physicians received a cover letter, the questionnaire, and a postage-permit return envelope sent first class in an outgoing metered envelope. We addressed the envelopes with a computerized self-adhesive address label with the last name first.

Nonrespondents to the first mailing were randomized into two groups. About half of the subjects received with the questionnaire a follow-up letter with a handwritten postscript which read as follows "Thank you, Doctor X, for your participation in the study." The other half received the same letter but no handwritten thank you note in the post-scriptum.

Nonrespondents to the second mailing were again randomized into two groups. One group was sent a mailout package which, instead of using the computerized address label with the last name first, had the physician's name and address individually typed onto the envelope with title preceding name (e.g., "Doctor John Smith" instead of "Smith, John"); 2) the outgoing envelope was identified to the university rather than to the survey title; 3) the outgoing envelope was handstamped rather than metered; and 4) the postage permit return envelope was replaced by a handstamped return envelope. The control group received the same mailout package as the one used earlier. As suggested by Dillman,[13] the data collection process was completed by a fourth mailing.

Results

Both techniques were effective in increasing physicians' response rates (Table 1). The handwritten post-script increased response rates by 40.7 per cent since 30.4 per cent of physicians in the handwritten post-scriptum treatment group responded compared to 21.6 per cent in the control group. The personalized mailout package proved even more effective: 39.5 per cent of physicians who were sent a personalized mailout package responded compared to 25.8 per cent for the control group. This represents an increase of 53.1 per cent.

Although specialists did not respond as well as general practitioners, they seemed somewhat more sensitive to the experimental variables (Table 1). In both experiments, the difference in response rates between the experimental and control groups was somewhat higher for specialists than for generalists.

Discussion

Achieving high response rates in physicians' mail surveys is often a challenge. Rates below 70 per cent are often reported in the literature.[14–17] In this study, we were able to improve physicians' response rates by using two relatively inexpensive techniques of personalizing the mailed questionnaire. The handwritten thank you note at the bottom of the letter accompanying the questionnaire increased physicians' returns by 40.7 per cent whereas the personalization of the mailout package proved even more effective, increasing returns by 53.1 per cent.

The techniques were more effective among physicians less interested in the survey topic (the specialists). Although one cannot exclude a regression to the mean effect, the results may suggest that specialists were particularly sensitive to efforts made to gain their collaboration.

PS⁺: Group exposed to the handwritten post-scriptum
PS⁻: Control group
PER⁺: Group exposed to the personalized mailout package
PER⁻: Control group

Even though personalization was undoubtedly effective in increasing physicians' returns, it is unclear why it worked. It is likely that it plays at different levels by increasing the probabilities that physicians will open the mailout, read the cover letter, and accept to complete the questionnaire. As others have emphasized,[18,19] more research is needed to understand the principles underlying people's behavior in relation to mailed questionnaires and to uncover significant interaction among survey techniques, survey content, and population.

It has been suggested that personalization in mail surveys can be counterproductive under certain circumstances, especially when it raises doubts in subjects' minds about the anonymity of their responses.[20,21] This study shows that it can be very effective if used appropriately. In physicians' mail survey, personalization is a technique that should be considered, particularly in follow-up mailings.

How Free Care Improved Vision in the Health Insurance Experiment

NICOLE LURIE, MD, MSPH, CAREN J. KAMBERG, MSPH, ROBERT H. BROOK, MD, ScD, EMMET B. KEELER, PhD, AND JOSEPH P. NEWHOUSE, PhD

Abstract: We studied reasons for the improvement in the functional vision of enrollees receiving free care in the Rand Health Insurance Experiment. Among low income enrollees, 78 per cent on the free plan and 59 per cent on the cost-sharing plans had an eye examination; the proportions of those obtaining lenses were 30 per cent and 20 per cent, respectively. Visual acuity outcomes of low income vs non-poor enrollees were more adversely affected by enrollment in cost-sharing plans. Free care resulted in improved vision by increasing the frequency of eye examinations and lens purchases. (*Am J Public Health* 1989; 79:640–642.)

Introduction

Over half of the US population wears corrective lenses.[1] In 1972, Americans spent $352.2 million on visits to ophthalmologists[2] and, in 1977, $1.6 billion on optical goods.[3] In 1975, 20 per cent of Americans had out-of-pocket expenditures for optical care.[2] Among automobile drivers, vision impairments are a major cause of accidents.[4]

The Rand Health Insurance Experiment (HIE) demonstrated that cost sharing reduced the use of health services,[5,6] but participants receiving free care had better visual acuity at the experiment's end than did those randomized to cost-sharing plans.[7]

In this paper, we explain why enrollees receiving free care had better corrected visual acuity and describe the amount of care for correcting visual acuity that was received by a non-aged general population.

Methods

Health Insurance Experiment (HIE)

The Rand HIE, a randomized trial of cost sharing, was conducted between November 1974 and January 1982 in six cities, among 3,958 enrolled persons ages 14–61 in 2,005 families; 70 per cent were enrolled for three years and 30 per cent participated for five years. Details about study design, sites, and participant exclusions have been previously reported.[8,9] The sample was a random sample of six communities. With the important exception of those over the age of 61 at enrollment, the sample is otherwise reasonably representative of the United States population with respect to age, sex, income, education, proportion Black, and marital status. The age distribution of participants in the free and cost- sharing groups were equivalent: 13 per cent aged 14–17, 17 per cent aged 18–24, 30 per cent aged 25–34, 19 per cent aged 35–44, 13 per cent aged 45–54, and 8 per cent aged 55–61. Families were assigned to one of 14 cost-sharing plans that varied in the degree of cost-sharing. The primary variation was in the coinsurance rate: 0, 25, 50, or 95 per cent, but out-of-pocket expenses were limited to $1,000 per family per year with a reduced amount for low-income families. All plans covered ambulatory and hospital care, preventive services, dental services, mental health care, and prescription drugs. Vision services were covered, subject to varying cost sharing, as follows:

- One eye examination for refractive purposes per year;
- One pair of corrective lenses per year. There was an additional out-of-pocket cost for contact lenses, and sunglasses were not covered unless medically necessary;
- One pair of frames every two years, with a maximum payment based on the normal price of standard frames in that area. The coinsurance rate for these services was based on the coinsurance rate for a given plan. For example, if the coinsurance rate was 25 per cent, then 75 per cent of the charge for refraction, glasses, and frames was reimbursed.

This analysis considers all enrollees age 14–61 at enrollment who entered and remained enrolled for the entire duration of the study. It excludes enrollees who died during the study and those enrolled in the HMO (health maintenance organization) portion of the experiment.

Assessment of Vision Status

Enrollees completed a medical history questionnaire both at entry to and exit from the experiment. This included questions about use of corrective lenses, presence of vision problems in daily life (e.g., Can you read the newspaper? Can you recognize a friend across the street?), and history of vision care.

In addition, the proportion of enrollees with corrective lenses on entry was equivalent in the free and cost-sharing groups. A random 60 per cent of enrollees at entry and all enrollees at exit received vision tests with and without lenses. Each eye was tested separately with the Snellen Eye Chart or the illiterate E chart and with the Rosenbaum near vision card. Visual acuity when tested without corrective lenses was termed "natural" acuity; when tested with lenses "functional" acuity. Examinees who did not wear glasses and had natural far vision worse than 20/20 or who wore glasses and had functional far vision worse than 20/20 were tested for pinhole acuity.

Explicit quality-of-care criteria specific to vision problems were developed by a panel of physicians and were reviewed by ophthalmologists. These focused on both processes and outcomes of care, including the presence of impaired functional vision at the end of the experiment, and are presented in full elsewhere.[10]

Analysis

We constructed a tree (Figure 1) that considered the points at which vision could have been affected by free care. Each branch represents a path to normal or impaired vision. We defined our population of interest as the 2,399 enrollees with natural vision impairment at entry or exit. (This number differs slightly from that reported in Brook, *et al*,[8] because we considered enrollees with near or far vision impairment at

entry *or* exit). Because virtually no one in the experiment underwent a procedure to improve natural vision, such as cataract removal, we can assume that those with natural impairment at the beginning also had natural impairment at the end of the experiment and that the presence of such impairment was not affected by plan.

In this analysis, all cost sharing plans were grouped together into a single category, because the differences among cost-sharing plans with respect to vision outcomes were negligible.[9] Two-tailed T-tests were used to contrast variables on the free and cost-sharing plans.

Results

The prevalence of perceived vision problems at enrollment was 70 per cent on both free and cost-sharing plans. Those enrollees who perceived a vision problem were more likely to have an eye examination than those who did not, and those who both perceived problems and had their eyes examined were more likely to obtain lenses than those who did not perceive a problem but nonetheless received an examination (Figure 1).

TABLE 1—Effect of Cost-Sharing on Process of Care for Vision Problems

Measure	% on Free Plan (n)	% on Cost-sharing Plan (n)
Perceived vision problem	70 (579)	70 (1104)
Had eye examination if problem perceived	90 (519)	76* (843)
Purchased lenses if problem perceived and had eye examination	48 (250)	47 (398)
Purchased lenses if problem not perceived but had eye examination	41 (67)	36** (89)

*Difference 14% (95% CI 6, 22)
**Difference 5% (95% CI .1, 9.9)

Effect of Cost-Sharing on Care

Of those who perceived problems, 90 per cent on the free plan and 76 per cent on cost-sharing plans received an eye examination (Table 1). However, once eye examinations were performed on those who perceived vision problems, enrollees on free and cost-sharing plans obtained lenses with similar frequency. In contrast, enrollees who did not perceive a problem with their vision but who nonetheless had an eye examination were somewhat more likely to obtain lenses if they were on the free plan.

Poor enrollees, defined as those in the lower one-third of the income distribution, were as likely as non-poor enrollees to perceive problems with their vision (70 per cent and 71 per cent, respectively). Poor enrollees with natural impairment who were on cost-sharing plans were less likely to have an eye examination than those on the free plan. Moreover, conditional on having an examination, they purchased fewer lenses (Table 2). While these differences were also present for the non-poor, they were less pronounced.

We also studied those enrollees with functional near visual acuity worse than 20/40 at enrollment. Of this group, 8 per cent of the poor and 25 per cent of the non-poor on cost-sharing plans purchased lenses necessary to correct vision to 20/20, while there were no statistically significant

TABLE 2—Effect of Cost-Sharing on Vision Care for Poor and Non-poor Enrollees

	Free			Cost-sharing			Free Minus Cost-sharing	
	Poor (n)	Non-Poor (n)	Diff (95% CI)	Poor (n)	Non-Poor (n)	Diff (95% CI)	Poor (95% CI)	Non-Poor (95% CI)
Process								
% with natural impairment having an eye examination	78 (255)	86 (466)	8 (3,3)	59 (285)	74 (808)	15 (9,21)	19 (12,26)	12 (10,14)
% with exam and with natural impairment who purchased lenses	30 (82)	43 (235)	13 (6,20)	20 (98)	35 (389)	15 (11,19)	10 (4,16)	8 (3,13)
Outcome								
% who obtained lenses during the HIE if functional near vision at enrollment was 20/40 or worse in one or both eyes	18 (49)	22 (76)	4 (−3,9)	8 (74)	25 (147)	17 (13,21)	10 (5,15)	−3 (−9,3)
% with exit functional far visual acuity equal to or better than pinhole acuity	80 (340)	83 (622)	3 (−2,8)	76 (594)	81 (1275)	5 (2,8)	4 (0,−8)	2 (−1,4)

differences in the purchase of lenses between poor and non-poor on the free plan (Table 2).

At exit, somewhat fewer poor than non-poor enrollees on the cost-sharing plans had their vision maximally corrected, while the difference in visual acuity between the poor and non-poor groups on the free plan was a bit less (Table 2).

We compared results (i.e., whether vision was corrected) by plan type for enrollees who received a vision examination at entry and those who did not. Unlike the results for a similar analysis in hypertensives,[11] this demonstrated that differences in the screening entry examination did not improve the exit vision outcomes.

Table 3 shows the mean number of visits to an ophthalmologist or optometrist during the three years of the experiment. Both visits and lens purchases were more frequent for enrollees on the free care plan. In addition, high income enrollees received more vision care than did low income enrollees.

Discussion

It was previously reported that free care resulted in improved vision. One possibility was that participants on the free plan obtained corrective lenses more often than those on the cost-sharing plans. This was true for low-income enrollees. Our analysis suggests that a different mechanism accounted for improved vision in the general population—more eye examinations. It is also noteworthy that visual acuity outcomes for low-income enrollees were adversely and differentially affected by cost-sharing.

In contrast to hypertension,[11] there was no favorable effect of the entry examination on vision outcome in the cost-sharing group. This may be due to the fact that entry examination results were reported only to the enrollees' primary physician, not to their optometrist or ophthalmologist. The enrollee's primary physician may have been less likely to act upon a report of vision results than upon a report of poor blood pressure control.

The explanation that more frequent visits led to improved outcome held for three conditions: vision impairment, hypertension, and dental problems. All three of these conditions are relatively common and inexpensive to diagnose and treat. It is probable that the increased visit rate on the free care plan resulted in increased detection of these diseases. This effect was most pronounced for low income enrollees.

TABLE 3—Use of Services for Vision in the HIE Sample Over a Three-Year Period

	Poor			Non-poor

Financing Disposal of Non-municipal Wastes: A National Seminar

The Energy Bureau has announced a one-day seminar entitled "Financing Disposal of Non-Municipal Wastes"—an intensive program focusing on such wastes as medical and hazardous wastes, as well as municipal and industrial sludge. To be held at the Radisson Park Terrace Hotel in Washington, DC, on May 18, the seminar leaders will discuss and analyze the changing regulatory environment applicable to these wastes; their liability framework; financial issues for lenders, for real property acquisition, and for transportation, storage and disposal; as well as financing models, such as public and not-for-profit issuers, project finances, pooled financings and public/private partnerships; key risk management issues, such as insurance, change of law, site conditions, and waste stream control; and technological responses, such as incineration, fluidized bed construction, bioremediation and recycling. For further information, contact: Robert W. Nash, president, The Energy Bureau, 1133 Broadway, New York, NY 10010. Tel: (212) 633-8011.

Reflections on Curative Health Care in Nicaragua

R. Giuseppi Slater, MD

Abstract: Improved health care in Nicaragua is a major priority of the Sandinista revolution; it has been pursued by major reforms of the national health care system, something few developing countries have attempted. In addition to its internationally recognized advances in public health, considerable progress has been made in health care delivery by expanding curative medical services through training more personnel and building more facilities to fulfill a commitment to free universal health coverage. The very uneven quality of medical care is the leading problem facing curative medicine now. Underlying factors include the difficulty of adequately training the greatly increased number of new physicians. Misdiagnosis and mismanagement continue to be major problems. The curative medical system is not well coordinated with the preventive sector. Recent innovations include initiation of a "medicina integral" residency, similar to family practice. Despite its inadequacies and the handicaps of war and poverty, the Nicaraguan curative medical system has made important progress. (*Am J Public Health* 1989; 79: 646–651.)

Introduction

Few developing countries have attempted fundamental revision of their health care delivery systems to enable them to truly serve the poor who form the vast majority of their population. Since its victory over the Somoza dictatorship in 1979, the Sandinista revolution in Nicaragua has placed great emphasis on improving health care and has received international acclaim for its achievements in public and preventive health.[1–3] After nine years, it is also important to see how well the present medical system meets the never-ending demand for curative medical care. A realistic examination of the Nicaraguan experience is important to better understand the difficulties and possibilities inherent in seeking such change.

This article is based on my personal experience working for a year in the regional hospital and in a neighborhood health center in the northern city of Estelí, as well as several months' work with the new Nicaraguan family practice residency program in Managua. It is also based on extensive visits to many other health facilities in Nicaragua and numerous conversations with health personnel, both Nicaraguan and foreign, at all levels of the health care system. To the maximum extent possible, I have attempted to supplement personal observations with reference to the limited data and published material available about Nicaraguan health care.

Three broad criteria can be used to assess health care delivery: access and affordability, efficacy in diagnosis and treatment, and effectiveness in coordinating with the preventive health sector. In simpler terms, how easy is it to get health care, how good is the health care, and how much does the health care seek to maintain health as well as restore it? Viewed from these perspectives, Nicaraguan health care is a mixture of successes and problems.

Access and Affordability

Before the revolution, only a limited number of Nicaraguans (primarily public employees and National Guard members and their dependents) had guaranteed access to government-supported health care.[3–6] For most of the population, obtaining health care meant cash-up-front. People in Estelí described to me how the hospital, in Somoza's time, had a three-tier admission system: those with a certain amount of money were admitted to large open wards and received limited therapy; those with more funds were placed in semi-private rooms; and those with ample resources had private rooms and a readily available physician. Hospital workers reported watching patients die at the emergency entrance because they lacked the admission fee.

Since the institution of the Unified National Health System (SNUS) three weeks after the victory of the Sandinista Revolution in 1979, health care in public facilities has been offered to all Nicaraguans at no cost.[2,3] To fulfill this commitment, the Nicaraguan Government first sought to train more health workers and build more facilities. In the first several years after the revolution, the medical school curriculum was revised to emphasize primary care issues.[7] A second medical school was opened, in Managua, and class size was expanded in the original medical school in León, resulting in a four-fold increase in medical school enrollment between 1979 and 1984.[3,7] By 1984, residencies had been initiated in 16 medical specialties and master's degrees were offered in Epidemiology, Public Health, and Hygiene; previously, no postgraduate medical training had been available in Nicaragua. Nursing schools were expanded and a new program was begun to train laboratory technicians.[6,8,9] The number of primary care health facilities more than tripled over one decade, increasing from 172 in 1977 to 472 in 1984 and to 588 in 1987.[6,10]

The impact of the contra war, including the resultant economic disruption, has slowed or reversed some earlier gains,[2,11] as has continued rapid population growth which currently averages 3.3% per cent per year despite significant emigration.[12] Figure 1 illustrates the initial marked increase in the quantity of health care providers per 100,000 population in Nicaragua after the revolution as well as the subsequent leveling off; Figures 2 and 3 show similar progress in increased utilization of health care services as well as the recent declines. Reflecting overall progress, including public health advances, infant mortality dropped from 121/1000 to 76/1000 live births between 1977 and 1983[2,11] and by 1986 declined to 64.5/1000.[12]

After the revolution, Nicaragua was divided administratively into six regions and three "special zones." For health care administration, each is defined as a "health region" (see Figure 4). A health region is subdivided into many health areas, throughout which are distributed health posts, the first line of primary care. They refer patients needing more advanced care to a smaller number of health centers located

in urban areas. Patients requiring hospital care go first to municipal hospitals, located in the larger towns. These in turn refer to the regional hospital, located in the principal city of the region. Managua and León, which have the nation's two medical schools, also have the national referral hospitals that offer tertiary care.

A typical health post is managed by a nurse, has a doctor at least part-time, handles acute and chronic illnesses, pre-

natal checks, well-child visits, vaccinations, and minor suturing and wound care. Sometimes an Oral Rehydration Unit is included, where babies and children with mild to moderate degrees of dehydration are observed and given packets of salt and sugar containing liquids (the World Health Organization formula, provided by UNICEF). There is no clinical laboratory testing. No appointment is required. Special efforts have been made to place health posts in the most underserved rural and urban sectors.

Health centers are staffed by doctors who may be

physicians just out of internship and completing two years of obligatory government service (an obligation common throughout Latin America) or by specialists (pediatrician, internist, etc.) completing residency training. There is on-site laboratory and x-ray equipment in a few health centers, and dentistry may also be offered. Some health posts and centers also have beds, where patients may be held for short periods of observation and treatment. In isolated areas, vaginal deliveries are performed in health centers. Patients are seen both by appointment and on a walk-in basis.

Municipal hospitals are staffed mainly by newly graduated generalist physicians completing their obligatory service, while regional hospitals have some specialists and, as teaching facilities, have intern staff as well. Although most of the physicians in outpatient facilities are Nicaraguan, there continues to be a shortage of Nicaraguan hospital physicians. Thus, in Region I (Estelí), more than 50 per cent of the hospital physicians in 1986 were international volunteers, mainly from Cuba but also from Western Europe, Canada, the United States, and other Latin American countries.* Of the 637 specialists in Nicaragua in 1987, 103 were foreign volunteers, nearly half from Cuba.** Cuba also provides generalist physicians completing obligatory postgraduate service who help staff health posts and centers as well as hospitals.

In practice, the system may not always function as planned. Although utilization of community-based facilities for primary care has increased greatly,[2] it is common in cities to see long lines outside hospital emergency rooms at 8:00 am while neighboring health posts may have only a trickle of patients. Some patients avoid the health posts and the centers and go directly to the hospital for ambulatory care because they feel the doctors may be more specialized (and thus better) or that more medicines or laboratory tests are available. While this is often true, the fact remains that, even in the hospitals, specialists are in short supply and medicines and laboratory tests are frequently unavailable.

People with money continue to utilize the private medical sector, which may provide up to 15 per cent of outpatient medical services.[3-5] In Nicaragua, the medical economy like the general economy is a mixed one; as in many developing countries, physicians tend to work mornings in government institutions and afternoons in their consultorios privados (private offices). Equipment and procedures absent in public medicine can often be found in private clinics, laboratories, pharmacies, and hospitals. In Estelí, private laboratories could often provide many clinical chemistry, blood cultures, and antibiotic sensitivity tests unavailable in the government hospital. Such services, though inexpensive by developed country incomes, cost at least the equivalent of several days' salary for an average Nicaraguan worker. Outside Managua and León, subspecialists such as urologists or otorhinolaryngologists are rarely found in the public sector, yet are readily accessible in private consultorios. Their fees limit access to those who can afford to pay them; sometimes payment in dollars is demanded.

For others, especially rural peasants and farm workers (campesinos) and people with less education, the traditional health care system of herbalists, curanderos, and lay midwives continues to be an alternative. Patients told me various reasons for consulting traditional healers: long-standing belief in their methods and medications, lack of access to more modern medical care in areas that are remote or destabilized by the contra war, and fear or distrust of doctors and hospitals.

*Sanchez E: Director of Planning, Region I Ministry of Health, Estelí, Nicaragua. Personal communication, 1986.

Diagnosis and Treatment

Although tremendous efforts have been made to increase the number of doctors and nurses, the demand for medical care is overwhelming now that free health care is deemed a right for everyone. Beyond the initial step of increasing the quantity of health workers is the even more difficult challenge of improving their training and work environment. The lack of clinical teachers and attending physicians, already acute because of the exodus of well-trained doctors after the revolution, is worsened by the contra war, which has caused diversion of resources and manpower, including medical manpower.[2] Finally, the poverty of the country, exacerbated by the enormous costs of the war, has restricted all efforts to improve the quality as well as quantity of medical attention.

Outpatient Care

Physicians in outpatient clinics I observed in five of the six regions and one of the special zones often see large numbers of patients—up to 50 in a four-hour period. Foreign physicians working in different areas confirmed my impressions that physical examinations are often rudimentary and examining rooms are commonly dark, noisy, and shared by several practitioners, separated only by small partitions. Most patients spend only a few minutes with the doctor and then receive four or five prescriptions.[13] Charting is rarely done, except for minimal obstetric and well-child records. Medicines are virtually free, but quantities are limited.

Outpatient medical care is uneven and variable in its effectiveness. Patients get little information or health education from physicians, leading to frequent noncompliance or miscompliance. Other foreign physicians as well as I have witnessed the unnecessary or inappropriate prescription of drugs and the inadequate or inappropriate treatment of chronic conditions. Much of the impetus for this polypharmacy comes from the patients themselves. The beliefs, so prevalent in Latin America, that more medicine is better, and that injections and infusions are more powerful than pills, create expectations among patients that physicians find difficult to resist.

Nevertheless, the majority of every-day problems are adequately diagnosed and treated. The Oral Rehydration Units are one of the great successes of outpatient care, and many a child has been spared hospitalization because of this widely available service; more severely dehydrated children are detected and referred to hospital in a timely manner. Extensive popular education campaigns have played a key role in the development of this program.[13]

Hospital Care

Hospital conditions vary enormously. In Estelí, the hospital is over 40 years old and was partially destroyed by the National Guard in 1979. Water is shut off in most of the hospital during much of the day; lights sporadically go off during surgery and the back-up system sometimes fails. The wards are large dark chambers; occasionally two people share a bed. One the other hand, cities like Bluefields (on the Atlantic coast), and Matagalpa and Rivas have newly built modern hospitals with some semi-private rooms, up-to-date

sterilizing equipment, steam laundry, overhead paging, and new x-ray machines.

My own observations of many Nicaraguan hospitals and the reports of other foreign physicians working in these institutions indicate that, despite the limited resources, common problems are usually handled adequately if not optimally. Problems arise with more complex illnesses, however, because of lack of training or diagnostic capability. Patients of any age with unclear diagnoses tend to be treated vigorously with multiple antibiotics and frequently with steroids. Emergency suturing is often done by people with little training, even for complex cosmetic lacerations, so that the wounds are closed but the scars are unsightly. Crisis situations are often poorly managed. Many of the worst problems of mismanagement come from the smaller hospitals that are staffed only by newly graduated physicians with no back-up.

Regional and municipal hospitals have no facilities or personnel for psychiatric patients. When acutely psychotic patients are hospitalized, they are placed in the medical wards with other patients. Hospital workers and physicians, with little training in psychiatric illness, are often reluctant to deal with them. The outpatient-based mental health workers (psychologists and social workers) make daily rounds and medicate these patients, but control methods are poor, so that such patients are sometimes tied to their beds or roam freely about the premises. In contrast, the national psychiatric referral hospital in Managua has succeeded in lowering its formerly overwhelming patient census by opening day treatment centers around the city and helping families to care at night for patients who are family members. This program will be applied nationally as soon as resources permit.[14]

Numerous factors contribute to the occurrence of clinical disasters. Medical training is spotty, because of limited resources. Medical students often have access only to outdated texts; many of their clinical teachers are social service doctors just out of internship and assigned to the medical schools. Basic skills in history–taking and physical examinations are limited. Experience with laboratory procedures is minimal so that many physicians regard any laboratory result as gospel, no matter how inconsistent it is with the clinical picture. Moreover, laboratory results are often unreliable and such basic tests as blood typing, hematocrit, and pregnancy testing are often unobtainable because of lack of reagents or equipment. Only a few clinical chemistries are available; bacteriology is limited to staining, serology to VDRL. Pap smears and biopsies require two to four months turnaround time (only León and Managua have pathologists) and, even so, approximately 25–30 per cent of the requests are never returned.

Other components of hospital care contribute to suboptimal results. Nurses and nursing aides, with little training in physical diagnosis, sometimes fail to recognize the ward patient who is deteriorating or developing complications. Vital signs are frequently done casually, and accurate fluid balance records are very hard to obtain.

The referral hospitals in Managua and León have somewhat more resources than the regional facilities, but intensive care units lack functioning monitors, blood gases are usually unobtainable because reagents are lacking, and diagnostic imaging capabilities include only basic x-ray and "sometimes-available" ultrasound. Chemotherapy or radiotherapy for cancer is limited, and no oral narcotics are available for terminal patients. Some medical problems can be diagnosed and treated only in other countries. Although Cuba and some European countries accept such patients, the process of referral is complicated, bureaucratic, and out of the reach of most patients.

The problems, errors, and shortcomings that affect medical care in Nicaragua are serious. Misdiagnosis and mismanagement are a significant cause of current morbidity and even mortality. Nevertheless, there is no question that most people have benefited enormously by the free medical care that is now available to all. The occasional dramatic failures are countered by the common unspectacular successes.

Linkage with the Preventive Sector

The outpatient health facilities should be a key link between curative and preventive health services because they provide both types of service, especially in the area of maternal and child health. Child nutrition has received special focus, and the health posts and centers seek to identify malnourished children, educate the mothers in such cases, and enlist them in special programs to receive supplementary food grants. For sheer lack of resources and trained personnel, especially health educators and social workers, results are uneven and it is not uncommon to see the same malnourished child return many times to the clinic or hospital. Clinic nurses, auxiliaries, and physicians have not been prepared for the preventive and educational aspects of health care; moreover, they are overwhelmed by other tasks. As an example, while oral contraceptives and IUDs (intrauterine devices) are dispensed, women learn little about their bodies and physiology or about the contraceptive methods they are given. In other programs, such as prevention of cervical cancer (the leading cancer in Nicaraguan women), the delays and frequent loss of Pap smear results minimize effectiveness.

There is no link between hospitals and preventive care. Part of the problem is lack of a standardized referral system. Patients often leave the hospital with little understanding of what happened to them during their stay. They receive brief written summaries (often just the discharge diagnosis) and are told to get follow-up care in the health post or center. Minimal patient education is done by hospital personnel, and there are no educators working in the hospital comparable to those working in the community where specially trained volunteers ("brigadistas") have been an important strategy of the Ministry of Health.[3–5] Social services are understaffed, making it difficult to obtain home evaluations for children with frequent hospital admissions for diarrhea and malnutrition.

One positive area is the promotion of breastfeeding. This was one of the first health priorities after the revolution, and postpartum women are given all available aid and encouragement to help them establish lactation, even when their babies are temporarily unable to nurse. Rooming-in was established in maternity wards in the early post-revolution years and the promotional distribution and advertising of commercial infant formulas were banned. Little data are available to support the general impression that more women are breastfeeding, however. Results of the few existing studies suggest that many women revert to bottle-feeding within the first four months.[15,16]

Discussion and Conclusions

Nicaragua, in the nine years since the Sandinista revolution, has developed a medical system that is physically and

financially accessible, offers care that is very uneven in quality, is generally adequate for most common problems, and is suboptimally coordinated with preventive health efforts. Such conclusions, however, must be viewed in a larger framework. It is vital to compare the present situation with pre-revolutionary conditions and with health care in the rest of Latin America to appreciate the achievements as well as understand the problems.

The present system is an immense improvement for the great majority of Nicaraguans, who previously had limited or no access to health care. Quality of care has probably decreased for those with wealth, but even in the Somoza epoch the wealthy (including the Somozas themselves) were quick to seek medical care outside Nicaragua when faced with serious illness.

Other Latin American countries have far more sophisticated medical capabilities than Nicaragua but, except for Cuba and Costa Rica, there is no other country that has managed to offer free curative health services throughout the country that reach even the most rural areas. The usual pattern is that physicians cluster in the cities and that services are often limited by access or the ability to pay.

Nicaragua in the 1970s was among the poorest of Latin American nations. Since the revolution, up to 10.9 per cent of the national budget has gone for health care,[10] but the poverty of the country continues to limit efforts to upgrade medical care. Phone communication is extremely difficult or impossible, paper is scarce, transportation is overcrowded, funds for equipment and maintenance are limited, and the situation is exacerbated by war.

Beyond the material deficits are the cognitive and psychological consequences of underdevelopment. Illiteracy was reduced from over 50 per cent to less than 13 per cent soon after the revolution,[1] but many people have only rudimentary reading and writing skills. Fatalism and inertia based on past experience must be overcome; long-established but questionable hospital routines require change and patients with chronic disease must be convinced to continue therapy.

The American economic embargo imposed on Nicaragua in 1985 by President Ronald Reagan has had major effects on the health care system. Prior to the embargo, most medicine and medical equipment imported into Nicaragua was American. Although the embargo supposedly excludes medical material, in practice most American companies and shippers are no longer supplying Nicaragua. The consequences are readily visible: Kodak x-ray film processors stalled for lack of chemicals, blood-gas machines inactivated by lack of parts, American microscopes unusable without replacement bulbs. Moreover, the costs of the economic sanctions to the Nicaraguan economy have meant less funds available for health.

The effects of the contra war on the health care system include the intentional destruction of facilities and deliberate killing of health personnel.[2,11,17-19] The war has also diverted resources destined for health care, displaced large numbers of people, and disrupted health services in the northern areas of the country.[2,11,20] In Estelí, I attended women arriving from war zones with complications of high-risk pregnancies who had been unable to obtain ongoing prenatal care for their underlying diabetes, renal insufficiency, or hypertension because the health facilities in their area had been destroyed or travel was dangerous because of contra mining of roads.[21] Estelí itself had been scheduled for construction of a new hospital in 1986; the site had already been prepared but the costs of the war forced cancellation of the project.

Even without the war, improving curative health care in Nicaragua would have been more difficult than developing the public health sector. The minimal existence of a public health system in Somoza's time allowed the new government to build a new one almost from scratch, whereas it was necessary to contend with an already entrenched medical care system and hierarchy when planning and implementing new ways of delivering medical care. In addition, curative services require a much greater investment in training and technology than preventive services, so advances are necessarily slower.

Nicaraguan health officials, cognizant of all the above mentioned problems, continue to apply new approaches to better the system, especially to improve clinical training and continuity of care.[22] The internship year, previously spent entirely in the hospital, was recently changed to add a 10-week block of training in a health center because internship is followed for most graduates by two years obligatory service in outpatient facilities. Health centers in Managua are now being kept open 24 hours a day to relieve the burden on hospital emergency rooms. Standardized forms have been introduced to summarize the obstetric history and outcome of parturient women and to specify and record vaccination schedules for their infants; these forms are distributed to women after delivery. In Estelí, a government-sponsored Center for Natural Childbirth offers free prenatal classes preparing women and their partners with Lamaze and other instruction for a better birthing experience. It has been so successful that similar centers will be opened around the country. Also in Estelí, a "Rescue of Popular Medicine Project" has involved the systematic classification and evaluation of herbal medicines and other natural remedies to determine whether they are effective enough to replace imported pharmaceuticals, thus saving precious foreign exchange. This project also is being expanded to other regions. A carefully constructed National Medical Formulary of less than 500 agents was instituted in 1985 to foster more rational and economic distribution and utilization of conventional pharmaceuticals at different levels of the health care system.

Perhaps the most important development is a new residency training program in "medicina integral." Health planners were concerned that too many specialists were being trained and that three-fourths of all practicing physicians were hospital-based, with excessive concentration in the most urbanized regions (León and Managua).[23] In response, they developed a three-year program that borrows heavily from Western family practice concepts but also includes emphasis on public health and administrative training. The residency training will aim at producing physicians with broad skills who can manage the municipal and regional hospitals and the larger health centers as well as staff isolated rural facilities. These physicians will be trained in the management of common problems, including surgical procedures such as cesarean sections and appendectomies, but they will also be able to recognize, stabilize, and refer more complex conditions, including acute psychiatric illness. The curriculum begins with an intensive block designed to improve skills in history–taking, physical examination, laboratory utilization, and appropriate medication prescribing. The long-range plan is to make these new "médicos integrales" the cornerstone of the system, thereby improving the distribution and continuity of care.

On a personal level, doing medical work in Nicaragua is

deeply gratifying despite the limitations and frustrations. Socioeconomic status is not a consideration in treating patients, nor is there any subtle prejudice against the poor. There is remarkable patience in the face of constant inconvenience and hardship. A democracy of scarcity prevails: patients of all walks of life are together on the wards, while hospital personnel share all facilities equally, including meals in the same dining hall. Young physicians are eager for teaching and support. In general, there is a sense of unity and common purpose among health workers and patients that helps everyone tolerate the difficult conditions.

Improving curative health care in third world countries has received much less attention in recent years than improving public health. Still, the need for medical care will always exist, and the availability and adequacy of such care is highly visible to the general population, which may influence public confidence and participation in preventive efforts. New strategies are necessary for developing nations seeking to create, with limited resources, health care delivery systems truly responsive to national needs. Despite the obstacles of poverty and war, Nicaragua has made considerable progress in this area. For a poor person in need of medical care, Nicaragua today is a much better place than eight years ago and better for such a person than a great many other Latin American countries.

ACKNOWLEDGMENTS

New Journal Launched: *AIDS Education and Prevention*

The first issue of the official journal of the International Society for AIDS Education was recently released by Guilford Publications, Inc. Entitled *Aids Education and Prevention*, this interdisciplinary journal is committed to providing professionals with the state-of-the-art information they need. It will publish high-caliber contributions that highlight existing and theoretical models of AIDS education and prevention, including their development, implementation, and evaluation.

The journal will address the distinct problems of various populations under the threat of AIDS. Also, the journal will cover various public health, psychosocial, ethical, and public policy issues related to AIDS education and prevention. Regular features will include scientific research, reports from the field, critical reviews of major problem areas, reports from meetings, book and video reviews, and a community bulletin board listing conferences, seminars, and meetings.

Price per volume of the quarterly journal is $30 (individuals and nonprofit AIDS service organizations); $60 (institutions). The publisher, Guilford Press, is at 72 Spring Street, New York, NY 10012. The editor, Francisco S. Sy, MD, DrPH, is Associate Professor of Epidemiology, School of Public Health, University of South Carolina, CARE Project, Columbia, SC 29208. Tel: (803) 777-2273.

Use of Clinic versus Private Family Planning Care by Low-Income Women: Access, Cost, and Patient Satisfaction

STEPHEN E. RADECKI, PHD, AND GERALD S. BERNSTEIN, MD, PHD

Abstract: Use of private physicians versus public family planning facilities by poverty level and near poverty level women was examined by means of a sample survey conducted in low-income areas of Los Angeles County. Utilization differed by race/ethnicity, with Hispanics more likely to go to federally subsidized family planning clinics (primarily county-run), Whites and Blacks to private physicians. Private family planning offers easier access, greater convenience, and higher satisfaction, albeit at almost double the cost. Clinic usage is influenced by lack of a regular source of medical care and lack of insurance coverage more than poverty level per se. Clinic patients report greater patient education regarding contraceptive methods, but less general medical care during clinic visits. They are more likely than private patients to express a desire for a different source of family planning care. (*Am J Public Health* 1989; 79: 692–697.)

Introduction

A shift over the course of the last two decades toward the use of more effective types of contraception requiring a physician or clinic visit[1] has fostered increased attention to utilization of formal family planning services, particularly for low-income populations and other subgroups with higher than average fertility rates.[2] For approximately 15 years, federally subsidized family planning clinics have been providing care at low cost to the patient. These clinics provide contraception and other services primarily to low-income populations[3] that might otherwise have limited access to reproductive-related care.[4] Yet, data from cycle II of the National Survey of Family Growth (NSFG) show that the percentage of women below the poverty level who obtain family planning care from private sources (rather than from subsidized clinics) ranges from 40 percent and 44 percent for Hispanics and Blacks, respectively, to 75 percent for Whites.[5]

The use of private sources of family planning care by a substantial minority of Black and Hispanic women below the poverty level, along with the pronounced difference in use of private care by poverty-level Whites, suggests the presence of determinants of private versus public sources of care other than poverty level per se. Cycle III of the NSFG (which incorporated both married and unmarried women) reported that provider choice was influenced by insurance coverage, with women who had no insurance (private or public) more likely to use subsidized clinics.[6]

Factors predictive of sources of family planning care, however, do not fully explain differences in utilization. In this study, survey data stratified by poverty level (below poverty, 100–149 percent of poverty, and 150+ percent poverty) and race/ethnicity (White, Black, Hispanic) are used to examine demographic precursors of the choice of provider for family planning care. We examined factors related to access, cost, and satisfaction with care received from clinic and private sources, as well as reported levels of patient education provided by different sources of care and the comprehensiveness of medical care available at each source.

Methods

Study Population

We conducted a population-based survey of poverty level and near-poverty level women residing in Los Angeles County. The target population was defined as women 18–44 years of age, or under age 18 if married or cohabitating. The survey employed a stratified random sample, with strata defined by race/ethnicity (White, Black, or Hispanic) and poverty level (below poverty, 100–149 percent poverty, or 150+ percent poverty). In order to ensure sufficient numbers of respondents from the two lowest poverty level strata, sample census tracts were drawn from among those in which more than 60 percent of the households were below 200 percent of poverty in the 1980 census.

Data Collection

A "screening questionnaire" determined participant eligibility and served as the basis for categorizing respondents into the sampling strata enumerated above. All respondents had visited a doctor or clinic for family planning care within a three-year period prior to the time of the interview. The screening questionnaire also served as the basis for stratifying the sample into equal numbers of White, Black, and Hispanic women, as well as equal representation of the three poverty level strata. The Asian population was excluded. Poverty level was determined by income/family size charts based on federal poverty criteria.[7]

Female interviewers conducted the interviews with respondents at assigned addresses in each census tract by means of a detailed survey instrument. The survey covered utilization of family planning services as well as other areas related to contraception and reproductive health. The screening questionnaire assisted the interviewer in identifying an eligible respondent (if any) within the household and selecting one woman in the household if more than one was eligible.

The average annual income for households below the poverty level was $7,348; for those from 100 to 150 percent of povery, $11,794; and for those in the open-ended 150+ percent poverty stratum, $22,309. Racial/ethnic differences in income occurred only in the third poverty stratum, where average income ranged from $18,322 for Blacks to $25,319 for Whites. When a respondent met all eligibility requirements and fell into a survey stratum not yet filled by the required number of respondents, the main interview was conducted. Field work for the survey was conducted between November 1984 and April 1985 and resulted in a total of 454 respondents—a response rate of 83.1 percent. The 16.9 percent nonresponse is comprised of refusals by eligible respondents (7.5 percent) combined with an

additional 9.4 percent "indirect" refusals representing non-screened households in which residents were inaccessible due to a security building, were not home after repeated attempts, or refused to provide screening information. (The latter figure was determined by multiplying the number of non-screened households by the probability of finding an eligible respondent in a screened household).

Survey Variables

The survey interviews, 29 percent of which were conducted in Spanish, cover the respondent's usual source of medical care, her insurance coverage and a number of other health and fertility-related areas. The "source" of family planning care was identified based on the respondent's report of where she went on her most recent visit for family planning care or advice. For approximately 80 percent of respondents, this visit had occurred within the preceding year.

From respondent information regarding name of facility, location, and the physician's name, sources of care were identified as one of four types.

- Subsidized clinics receive state and federal funding through the Los Angeles Regional Family Planning Council. Composed primarily of large, county-run clinics, but also including such organizations as Planned Parenthood, these clinics provide family planning care to low-income women on an income-based sliding scale.
- Private clinics receive no subsidy but typically accept Medicaid payment. These include both specialty and general clinics where patients do not have a regular physician.
- Health Maintenance Organizations (HMOs) are prepaid plans such as Kaiser Permanente, Maxicare, etc.
- Private physicians are non-prepaid doctors in solo or group practices.

Care facilities out-of-state or in Mexico were designated as "other."

A substantial portion of the interview elicited information on characteristics of the family planning care received at the respondent's source of care, including both objective and subjective measures of patient satisfaction, patient education, provision of preventive care, and cost. The analysis presented here contains comparisons of these utilization and satisfaction measures across clinic and private sources of family planning care.

Results

The distribution of respondent characteristics by race/ethnicity and poverty level (Table 1) reveals that: respondents in the highest income group are oldest; Hispanics are most likely to be married; high parity is associated with Hispanic ethnicity, and with incomes below the poverty level. Expected racial/ethnic differences in religious preference were also demonstrated.

Table 2 shows that 25.8 percent of the study's respondents are currently utilizing subsidized family planning clinics, 15.6 percent use private clinics, 18.5 percent use HMOs, 35.5 percent use physicians in private practice, and 4.6 percent use sources in other states or Mexico. This pattern of utilization does not vary by poverty level, but 41.9 percent of

Hispanics utilize subsidized clinics, compared to 18.2 percent of non-Hispanic Whites and 12.3 percent of Blacks. Poverty level and race/ethnicity interact (Figure 1). Hispanics below the poverty level are twice as likely to utilize subsidized clinics compared to those above poverty; for Hispanics below poverty, these clinics account for almost two-thirds of all family planning care.

In Table 3, the percentage respondents with a regular source of medical care ("one person or place in particular you usually go to when you are sick or want advice about your health") and the percentage with insurance coverage are compared by source of family planning care and by race/ethnicity and poverty categories. The percentage reporting a regular source of medical care is substantially lower for those using both subsidized and private clinics compared to HMOs and private physicians, for all strata. Women who utilize subsidized family planning clinics are substantially less likely to have either private or public insurance coverage compared to those who utilize other sources. Less than one-third of subsidized clinic patients have any coverage, compared to half of those utilizing private clinics, more than three-fourths of those with private physicians, and more than nine-tenths of those who utilize HMOs.

Comparisons across race/ethnicity and poverty level

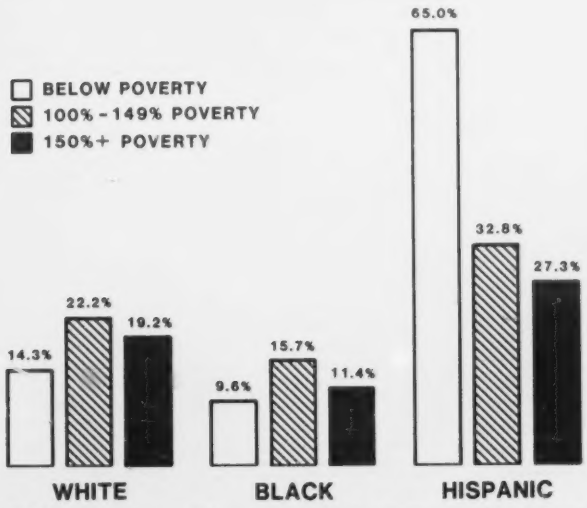

FIGURE 1—Percentage of Respondents within Racial/Ethnic and Poverty Level Categories Utilizing Subsidized Family Planning Clinics, Los Angeles County Survey

show differences in insurance coverage within each group between patients of private physicians and those who utilize clinics. Hispanics are substantially less likely to have insurance than are Whites and Blacks (47.6 percent compared to 72–73 percent). At 64 percent, the level of private/public health insurance reported by poverty level women is identical to that found for poverty level respondents to the National Health Interview Survey.[8] But the percentage of respondents with insurance does not increase significantly for those above the poverty level in this low-income population.

A number of other characteristics not shown in Table 3 were compared across a patient's source of family planning care and found to have a small or inconsistent relation to type of provider. These include the woman's age, her level of education, marital status, employment status, religion, length of residence in the Los Angeles area, and number of pregnancies, live births, and abortions.

Table 4 presents measures of access to family planning care, the physical examination during the most recent visit, and the cost for that visit, along with indirect measures of patient satisfaction. The percentage reporting that an appointment was required ranges from 95.2 percent for HMOs to 80.7 percent for private physicians, with private and subsidized clinics falling in between. The average number of days between the time the appointment is made and the date of the visit exceeds 12 days for both subsidized clinics and prepaid plans, compared to 5.1 days for private physicians.

An average of 156.9 minutes is reported as the total visit time for subsidized clinics, compared to 91.0 minutes for private clinics, and 68–70 minutes for HMOs and private physicians. Subsidized clinics also have higher reported numbers of people in their waiting rooms, and are less likely to permit women to bring their children, compared to other sources of family planning care. Greater difficulty reaching the woman's provider by telephone is encountered with subsidized clinics, followed by HMOs, whereas private physicians and clinics are easiest to reach by telephone.

A series of questions designed to measure respondents' satisfaction with their source of family planning care (e.g., "I am usually able to come in at a time and date that are convenient for me") show highest rates of agreement (either "agree" or "strongly agree") with most of the favorable statements by patients of private practitioners, and highest rates of agreement with unfavorable statements on waiting times and crowdedness by patients of subsidized clinics (Table 4). Statements on costs and return visits did not differentiate among providers of care.

The actual cost of family planning care (Table 4) is reported

[a]Includes 21 respondents who reported "other" sources of care.
[b]These percentages are slightly lower than the sum of "private" and "public" percentages, as a small number of respondents reported having both types of coverages.

as the percentage of patients with no "out-of-pocket" costs, and the average dollar amount for patients who incurred some direct cost for the visit. Of patients of subsidized clinics, 28.3 percent had no direct cost, compared to 55.1 percent of patients of private physicians. For those who had some out-of-pocket expense, however, the difference in that expense is almost double—$18.20 for subsidized clinics compared to $32.80 for private physicians. This comparison excludes those who had procedures (including sterilizations) performed during the visit, along with a small number of respondents who were being seen primarily for a medical complaint.

Data on characteristics of the physical examination (Table 4) show a four-fold difference between patients of subsidized clinics and patients of private physicians in the percentage who reported that they have the same examiner at each visit. Waiting times for the examination range from just over 30 minutes for prepaid plans and private physicians to over 90 minutes for subsidized clinics; however, the average length of the examination does not differ by source of care.

Patient satisfaction items related to the physical examination show higher agreement with favorable communication/discussion statements by private practice patients, and higher levels of discomfort and embarrassment for subsidized clinic patients. Statements on completeness of the examination and consideration and gentleness of the examiner do not differentiate among providers. Finally, when respondents were asked if they would prefer a different source of care, 33.3 percent of subsidized clinic patients responded affirmatively, compared to 26.2 percent of those in HMOs and 15.5 percent of patients of both private physicians and private clinics.

Table 5 presents results from a question on the comprehensiveness of patient education on contraceptive methods, along with information on the source(s) of contraceptive patient education at the woman's source of care. Respondents were shown the list of family planning methods in Table 5 and asked to indicate whether each method listed had been discussed or explained to them at their source of family planning care. This family planning education could have occurred prior to the most recent visit, as virtually all respondents (91.5 percent) reported multiple visits within a three-year period to the place cited—a figure that did not differ by source of care. For each family planning method, subsidized clinics (followed in most cases by private clinics) are more likely to have provided an explanation than are HMOs and private physicians. Among the latter groups, approximately one-third of patients report having "no methods explained," compared to approximately 17 percent for subsidized or private clinics. Percentages for individual methods are likely affected by respondent recall, as subsidized clinics are required to provide information on all family planning methods. For those respondents who did report family methods explained during their visit, Table 5 shows the means by which the methods were discussed or explained. While the respondents' perceptions of types of health personnel may not be entirely reliable, it is clear that for those using HMOs or private physicians, the physician predominates as the source of information; whereas for subsidized and private clinics the source of information is more likely to be a nurse, nurse practitioner, counselor, or a film or videotape.

Finally, respondents were also asked if they thought that they could receive care for each of a list of common problems while obtaining family planning care. The list of problems was derived from data on the most common patient complaints in ambulatory primary care from the National Ambulatory Medical Care Survey.[9] Some complaints that suggested the possibility of a side effect of a birth control method were eliminated. Results of this comparison, not shown in the

TABLE 4—Access to Care, Characteristics of Examination, Satisfaction and Cost, by Source of Family Planning Care

Percentage Who Would Prefer A Different Source of Care	33.3	15.5	26.2	15.5

[a]Respondent usually has to have an appointment, as opposed to "walk-in" care.
[b]Possible responses to each statement were "strongly agree," "agree," "disagree" or "strongly disagree."
[c]Cost measures exclude patients who reported sterilization as their family planning method.
[d]Not including what insurance pays for. Cost comparisons exclude out-of-pocket costs reported by respondents who had any type of procedure (including sterilization) performed and those whose visit was primarily for some medical complaint (rather than primarily for family planning).

Table, produced consistent differences, with patients of HMOs most likely to believe that they could receive care or advice for each of the problems listed, followed by patients of private physicians, and (lastly) those who utilize subsidized or private clinics. Data on Pap smear, breast examinations, routine laboratory tests and tests for sexually transmitted diseases (STD) (also not shown) indicate no significant differences by source of care in the percentage of women who reported having had these screening examinations and tests performed within the preceding 12 months.

Discussion

Our data indicate that the majority of low-income women in Los Angeles County obtain their family planning care from private sources—primarily private physicians. Subsidized family planning clinics account for the majority of care only for the sub-group of Hispanics below the poverty level. Clinic utilization is associated with a lack of a regular source of general medical care, but the single most powerful predictor of patterns of utilization was insurance coverage, including Medicaid. Further, the relation of insurance coverage to race/ethnicity helps to explain high rates of subsidized clinic use by Hispanic women.

The study has thus demonstrated variation in the use of clinic versus private family planning sources by race/ethnicity, an absence of effects based on poverty level, and the impact of insurance coverage as a barrier to unconstrained choice of providers. These patterns of utilization by race/ethnicity and poverty level in Los Angeles differ from those from cycle III of the National Survey of Family Growth, which showed substantially greater utilization of subsidized clinics by Blacks and women below the poverty level.[6]

Both surveys found insurance coverage (either private or Medicaid, eligibility for which is dependent upon both income

and legal residency status) to be a pivotal variable in explaining utilization of subsidized clinics versus private physicians. For women without insurance, subsidized clinics assume a crucial role in assuring access to family planning care. Differences in levels of utilization of subsidized clinics versus private care noted for the Los Angeles sample as compared to the national survey undoubtedly reflect regional variation in eligibility for Medicaid benefits used for private family planning care[10] as well as variation in both the organization and deployment of subsidized clinics, and the distribution of private practitioners across urban and rural communities.

The inclusion of a number of specific questions on convenience, cost, and satisfaction with the respondent's source of family planning care in the Los Angeles survey uncovered possible determinants of provider choice not considered in the national survey. Data on out-of-pocket expenses show that, although the cost of service from private physicians was almost twice that of subsidized clinics, over half of the patients of private physicians pay no out-of-pocket costs for visits as opposed to only about one-fourth of subsidized clinic patients, corroborating the role of lack of insurance coverage as a "barrier" to private family planning care.

Although there is no direct indication in our data of any differences in the quality of care among categories of providers, clinics are more likely to provide patient education for contraception. More importantly, a variety of patient satisfaction measures demonstrate why private family planning care will usually be sought by low-income women in Los Angeles when either private or public insurance is available. The detailed data on waiting times and other comfort and convenience factors associated with use of subsidized family planning clinics corroborate impressions obtained in a multicity telephone survey of low-income women, which showed that clinics were associated with less personalized and (according to respondent's criteria) "lower quality" care.[11] Our findings, although obtained from respondents in a single urban area, reinforce the importance of non-financial factors in determining levels of clinic utilization by low-income women, and point to specific areas (e.g., patient scheduling) in which efforts directed toward improvements in the provision of family planning services could be expected to yield benefits in terms of utilization and satisfaction.

Longitudinal Study of Physical Ability in the Oldest-Old

TAMARA HARRIS, MD, MS, MARY GRACE KOVAR, DrPH, RICHARD SUZMAN, PhD, JOEL C. KLEINMAN, PhD, AND JACOB J. FELDMAN, PhD

Abstract: Based on 1984 data from the Longitudinal Study on Aging, one-third of White persons aged 80 or older living in the community (N = 1,791) were defined as having no difficulty in walking 1/4 of a mile, in lifting 10 pounds, in climbing 10 steps without resting, or in stooping, crouching or kneeling. Physical ability was associated with lower risk of death over two years mean follow-up; Relative odds (RO) = .4 (95 percent confidence interval = .4, .6) and in survivors, lower utilization of hospitals RO = .4 (CI = .3, .7), physicians RO = .6 (CI = .5, .8) and nursing homes RO = .3 (CI = .2, .5) compared with those having difficulty on any of the four functional measures included in the definition of physical ability.

Fifty percent of the women and 42 percent of the men physically able at the time of the baseline survey in 1984 remained physically able at follow-up. Continued physical ability in this group was associated with never having had cardiovascular disease RO = 2.1, (CI = 1.2, 3.7), never having had arthritic complaints RO = 1.9 (CI = 1.2, 2.7), a body mass index less than the 75th percentile (RO = 1.8 (CI = 1.2, 2.9), younger age (for each decade of age, RO = 2.0 (CI = 1.1, 3.6), and higher level of education (greater than 13 years versus 0–6 years) RO = 2.4 (CI = 1.2, 4.7). These correlates include factors amenable to preventive measures and highlight the need to consider the heterogeneity of the oldest-old in formulating programs aimed at prevention and postponement of disability. (*Am J Public Health* 1989; 79:698–702.)

Introduction

Increased attention is being focused on the fastest growing segment of the United States population, the oldest old.[1] Much of this attention concerns disability,[2,3] use of health services,[4,5] and risks of institutionalization.[6,7] Recently, more optimistic views of old age have been proposed by those focusing on "successful aging"[5] who suggest that environmental and physiologic modifiers of biological aging can be identified which may be amenable to preventive strategies even among the oldest-old. However, few studies exist describing the correlates of "successful aging" or the factors which may govern transition from health to disability for the oldest-old.

Data from a longitudinal follow-up of those persons age 80 or older participating in the Supplement on Aging to the 1984 National Health Interview Survey conducted by the National Center for Health Statistics were analyzed to address three areas pertinent to public health policy for the oldest-old:

1. What proportion of persons aged 80 or older in the community could be considered physically able and what is the change in the proportion physically able over time?
2. What is the relation of physical ability at baseline to morbidity and mortality over time?
3. Can we identify correlates of maintained physical ability which would be amenable to health promotion in the oldest-old?

Methods

Study Population

The National Health Interview Survey (NHIS) is a continuing survey of civilian noninstitutionalized persons in the United States which includes information on health status, health care utilization, health conditions, and disability. In 1984, the Supplement on Aging, specifically directed toward persons age 55 or older,[9] was added to NHIS; 96 percent of eligible persons participated. Special efforts were made to achieve complete self-response from all supplement respondents; of those for whom data were obtained, 89.8 percent were self-respondents. Permission was obtained to link with administrative records maintained by the National Center for Health Statistics. In 1986, a follow-up was undertaken of all persons aged 80 or older and approximately half of those aged 70–79 who participated in the Supplement on Aging. Vital status was ascertained for potential respondents.[10] Those alive at follow-up were reinterviewed over the phone with questions excerpted from the original survey instrument. Again efforts were made to obtain self responses; 74.3 percent of interviews were self-responses.

Our study population is drawn from the 2,090 persons aged 80 or older in 1984 who participated in the Supplement on Aging. Blacks and races other than Whites were excluded as numbers were few. Of the original 1,932 White persons, 1,776 were either reinterviewed or known to be dead as of the 1986 follow-up. Fifteen persons who were not interviewed at follow-up but who were known to be alive in institutions were included. This resulted in a final study population of 1,791 White persons aged 80 or older: 1,214 women and 577 men.

Study Outcomes

Physical ability at both baseline and follow-up was defined as no difficulty in any of four measures which have been associated with assessment of ability to work.[11] These four measures included having no difficulty in walking 1/4 of a mile, in stooping, crouching or kneeling, in lifting 10 pounds, or in walking up 10 steps without resting. Only individuals with no difficulty on all four of these measures were considered physically able. Individuals missing data on any of the four functional measures were grouped with the comparison group as were those persons not interviewed but known to be living in nursing homes (missing values ranged from 1.6 percent for walking to 7 percent for lifting in the baseline interview and from 3 percent for stooping to 5 percent for climbing steps in the follow-up interview).

Mortality at follow-up was defined as death validated by a match with the National Death Index[12] for deaths through August 31, 1986 or report of death for 13 people for whom

Editor's Note: See also related editorial p 685 this issue.

information for a match was lacking. Death certificate information was not available. There were 338 deaths.

Three morbidity outcomes were defined for those alive and reinterviewed at follow-up. Hospital utilization was defined as two or more hospitalizations in the 12 months prior to reinterview in 1986. About 10 percent of the survivors had two or more hospitalizations; 5 percent were missing information on this variable. Nursing home utilization was defined as any nursing home utilization between the baseline interview in 1984 and reinterview in 1986. About 10 percent of the survivors had been or were presently in nursing homes and 3 percent were missing information on this variable. Heavy physician utilization was defined as six or more visits to the physician in the 12 months prior to reinterview (75th percentile). Twenty-five percent of the survivors reported six or more visits; 10 percent had missing data. Analyses presented in this paper exclude those with missing information on these morbidity outcomes.

To examine morbidity and mortality end points in relation to functional status, participants were classified into five mutually exclusive categories based on baseline functional status. The physically able group, the highest level of function, was used as the group against which risks were calculated. The four other categories included: those who received help from another person with one or more Activities of Daily Living (ADL) including bathing or showering, dressing, eating, getting in or out of bed or chair, walking, getting outside, using or getting to a toilet; those who had difficulty with Activities of Daily Living but did not receive help from another person; those who had no difficulty with Activities of Daily Living but did have difficulty with Instrumental Activities of Daily Living (IADL), i.e., preparing our meals, shopping for personal items, managing money, using the telephone, doing heavy housework, doing light housework; and those who were not physically able but had no difficulty on Activities of Daily Living or Instrumental Activities of Daily Living.

Change in Function

Those reporting a change in function for health or physical problem for difficulty walking a quarter of a mile or difficulty climbing 10 steps at follow-up were asked to define the main cause of change in function. These causes were compared for those physically able and the comparison group at baseline.

Correlates of Physical Ability

Variables examined in longitudinal relation to continued physical ability among those physically able at baseline included age, sex, social function (defined as phone contact with friends or neighbors within two weeks of interview), absence of hearing problems (defined as being deaf in one or both ears or having trouble hearing), absence of vision problems (defined as being blind in one or both eyes or having trouble seeing), no difficulty chewing, never having had hypertension, never having had diabetes, never having had arthritis or rheumatism, and never having had cardiovascular disease (stroke, heart attack, angina or other heart condition). Those responding "don't know" for any particular condition were considered to be free of the condition (less than 2 percent for any particular condition). Completed years of education were included as a categorical variable of 0–6 years, 7–8 years, 9–12 years and 13 years or more with 0–6 years as the comparison group. Missing values (2.5 percent) were imputed to the mean (8 years of education). Body mass index (weight in kilograms/height in meters squared) at baseline was calculated from reported weight and reported height and was included in the model as sex-specific quartiles of body mass index with the heaviest quartile as the comparison group. Missing values (less than 1 percent) were imputed to the mean for each sex, (23.7 kg/m^2 for men and 23.6 kg/m^2 for women).

Statistical Methods

The design effects, which represent the effect on the variance of using a clustered rather than a simple random sample, were small for each sex in this sample[9]; the inclusion of age in the models reduced the design effects further. The analyses in this paper are not adjusted for the complex sample design.

Logistic regression models were used to derive estimates of effect for analyses related to physical ability or to morbidity outcomes in those surviving from baseline to follow-up. All analyses were adjusted for age (as a continuous variable) and sex. Potential confounding by length of follow-up was controlled for by inclusion of a time variable calculated by subtracting the date of initial interview from date of follow-up interview. For analyses related to death, proportional hazards models were calculated with follow-up time defined as time from baseline interview to time of follow-up interview or date of death from National Death Index match. Mean follow-up time was 1.9 years. Survival analyses were not performed for risk factors for death among only those physically able at baseline due to the small number of deaths. Estimates of risk were derived from the coefficients in logistic or proportional hazards models and 95 percent confidence intervals were calculated.[13]

The independent variables were designed to express the association of a positive outcome with the unexposed state of a risk factor since the outcome in these analyses was physical ability—a positive outcome. For example, the relationship of physical ability to hypertension was assessed by contrasting risk in never hypertensives against risk in hypertensives, contrary to the customary expression of relative risk in epidemiologic studies.

Interactions with sex were observed for hearing problems ($p = .03$) and the social function ($p = .08$) variable. Final models included sex-specific indicator terms for these variables. No other significant interactions by sex were noted (P values ranged from .23 to .94); therefore, data are presented for men and women combined.

Results

Physical Ability at Baseline

In 1984, 33 percent of 1,791 noninstitutionalized White persons aged 80 or older, 44 percent of the men and 28 percent of the women, met the definition of physical ability (Figure 1). The order of difficulty for the four items included in the definition of physical ability was similar for men and women, although women were more likely to have difficulty on each item. Sixty-seven percent of all White persons aged 80 or older living in the community had no difficulty lifting 10 pounds, 57 percent had no difficulty climbing up 10 steps, 49 percent had no difficulty walking 1/4 of a mile, and 47 percent had no difficulty with stooping, crouching or kneeling.

Seventy-six percent of the physically able had had no hospitalizations and fewer than six doctor visits in the 12 months prior to baseline interview versus 55 percent of the comparison group, reflecting the better overall health status of the physically able persons. About 2 percent of the physically able had two or more hospitalizations in the 12

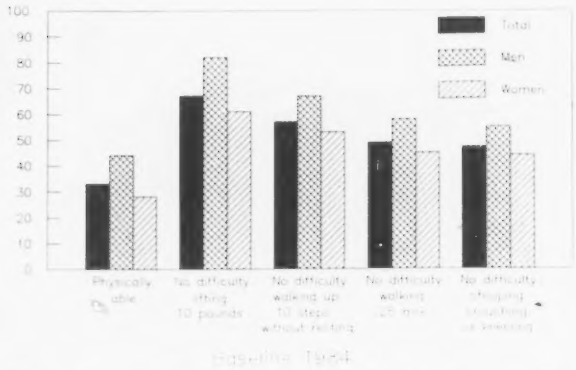

FIGURE 1—Physical Ability of Noninstitutionalized White Persons, Age 80 or Older

months prior to the baseline interview contrasted with 10 percent in the comparison group.

Longitudinal Follow-up

Fifty percent of the women and forty-two percent of the men who were physically able at baseline continued to meet the criteria for physical ability at follow-up (Table 1). The proportion of the comparison group dead by follow-up was twice that of the physically able group. Of the 1,453 persons alive at follow-up, 25 percent were physically able, 33 percent of the men and 22 percent of the women.

Cardiovascular conditions were the main problem reported to cause change in ability to walk 1/4 of a mile or in the ability to climb 10 steps among those physically able in 1984 (Table 2). Cardiovascular problems and multiple conditions were about equally important in terms of accounting for change in the comparison group.

Those receiving help with any ADL at baseline interview were four times more likely to die. Among the survivors, they were six times more likely to have used a nursing home during the following two years and at least twice as likely to have two or more hospitalizations or to have had six or more physicians visits in the year prior to reinterview than those physically able in 1984 (Table 3). Although risks of each outcome decreased as level of functional ability increased, even those only nonrobust without ADL or IADL difficulty were at increased risk in comparison with the physically able particularly for hospitalizations or nursing home admissions. When all those with missing data were considered as low

users of services, outcome results were substantially the same.

Correlates of Continued Physical Ability

Never having had cardiovascular disease and never having had arthritis at the baseline were associated with almost twice the likelihood of continued physical ability as was a body mass index below the 75th percentile (25.4 kg/m^2 for men and 25.2 kg/m^2 for women) (Table 4). Men were more likely to remain physically able. The same multivariate models showed higher education and younger age also were associated with continued physical ability. Several other characteristics were consistent with continued physical ability (no hearing problems in women, speaking on the phone with friends or neighbors in the two weeks prior to interview for women, no difficulty chewing, and no hypertension) although the confidence intervals for these variables did not exclude 1.0. When these analyses were recalculated considering those physically able individuals lost to follow-up (n = 41) as either physically able at follow-up or not, results were unchanged.

Discussion

Based on data from a national survey of noninstitutionalized older persons, about one-third of White persons age 80 or older living in the community had a high level of functional capability. This functional capability, which we call physical ability, appears to be associated with good health and low risk of morbidity and mortality over short-term follow-up.

Continued physical ability among those physically able at baseline was associated with lack of cardiovascular disease or arthritis, and moderate body weight. The prominence of cardiovascular disease and arthritis in these analyses was similar to data from other surveys[14,15] as well as data on bed disability, hospital utilization, and physician contacts.[16] Little data exist on the relationship between weight and morbidity for the oldest-old. It would be useful to evaluate our findings in a data set with measured weight and height. Our ability to explore other issues related to transitions in health status will be enhanced when linkages of the Longitudinal Study of Aging and Medicare records are in place and cause-specific mortality data are available from death certificates.

Although others have studied good health or longevity as an outcome in old age,[17,18] there have been few studies of longitudinal correlates of high level function among the oldest-old. A recent paper from the Framingham Heart Study

examined good function as an outcome over 21 years of follow-up in a group of 1,474 persons aged 35–68 at baseline.[19] Level of education was the only consistent predictor of good function for both men and women. That study, like ours, used physical function to define the outcome. Correlates of good function were examined in a group presumed to be at a high level of function at baseline. However, the Framingham study contained few very old persons at follow-up (n = 147 for those age 76 or older). Furthermore, their analysis defined long-term risks of good function in old age; our study examined short-term risks of remaining functionally able in very old age. As the US population becomes older, an understanding of how to remain healthy from younger life is critical; however, just as critical is an understanding of remaining as functionally fit as possible in the last years of life.

The consistent finding that level of education is related to good function is of interest despite the differences in study design and our inability to control for behavioral variables (such as cigarette smoking or alcohol consumption) or measured biological variables (such as blood pressure). Education may reflect life-long access to medical care or healthful habits, but may also relate to current practices. Even in old age, persons of higher educational status report use of more preventive health services than their less educated peers.[20]

Health policy research in aging is frequently directed toward the high cost users of medical care, those who are very ill or those in institutions.[4,7] For health promotion and disease prevention to be most effective in old age, the emphasis may need to shift from the very disabled old to the less disabled population at high risk of developing disability. A recent NIH conference on geriatric assessment highlighted the need for targeted intervention strategies[21]; those with impairments of walking, climbing, stooping, or lifting but without difficulty on ADL or IADL may define such a group with incipient problems. In fact, among those without ADL or IADL problems at baseline in 1984, those non-physically able were at twice the risk of developing a problem with ADL or IADL at follow-up, RO = 2.1 (CI = 1.6, 2.9) compared with the physically able. Our analysis also showed risks of institutionalization, hospital use or death to be greater in this group in comparison to the physically able.

Our criteria were restricted to physical ability because we were interested in defining higher level function to be comparable to Activities of Daily Living and Instrumental Activities of Daily Living, both of which emphasize motor function. There is a need for work to examine and redefine higher level function in old age to include dimensions other than pure physical function.[22]

Despite our intention to choose measures equally applicable to both sexes, women consistently reported more difficulty with each physical activity, the largest difference was observed for difficulty lifting 10 pounds. The interpretation of this difference by sex is unclear but is consistent with other data for the old-old.[23] Whether differences in reported difficulty relate to true differences in physical ability or gender-specific styles of interpretation of these types of questions is unclear.

A potential methodologic problem arises in that a large proportion of persons reported as physically able at baseline no longer met the criteria for physical ability at follow-up and a much smaller percent of those not physically able at baseline were physically able at follow-up. Whether such dramatic changes occur in functional status for populations of very old persons over short periods of time will be clearer as additional follow-up is completed. This finding highlights problems with functional status measures[24,25] as these measures capture not only the "true" measurement of function but variation due to factors such as acute health status and response set. Others have noted that change in functional patterns may be particularly difficult to delineate due to the

subjective nature of the measure.[26] There is a critical need for methodological work to assess measurement of true change in status from other sources of intra-individual variation.

These data suggest a substantial proportion of persons aged 80 or older have no functional impairments and maintain that status over short-term follow-up. Risk factors associated with continued physical ability included weight, arthritis, and cardiovascular disease, factors which may be amenable to intervention. Additional longitudinal follow-up and analysis of medical utilization data will provide the opportunity to continue to examine the relationship of physical ability to morbidity and mortality over time.

Predictors of Healthy Aging: Prospective Evidence from the Alameda County Study

JACK M. GURALNIK, MD, PHD, AND GEORGE A. KAPLAN, PHD

Abstract: Long-term predictors of high levels of physical functioning were examined in a representative sample of Alameda County, California residents followed from 1965 through 1984. The cohort investigated in this study was born between 1895 and 1919, with survivors being age 65 to 89 at the time of follow-up. A scale of physical functioning was developed from a comprehensive set of questionnaire items which assessed the full spectrum of physical functioning. Those scoring in the top 20 percent, defined as healthy aging, were compared to the remainder of the cohort, including those who died and those with lower levels of functioning at follow-up. After adjustment for age and functional status at baseline, the following variables were predictive of high functioning at follow-up 19 years later: race (those not Black), higher family income level, absence of hypertension, absence of arthritis, absence of back pain, being a non-smoker, having normal weight, and consuming moderate amounts of alcohol. Sex did not predict high function because of the counterbalancing effects of higher survival in females but greater likelihood of high functioning among surviving males. (*Am J Public Health* 1989; 79:703–708.)

Introduction

There have been dramatic improvements in life expectancy in this century, and mortality declines in the population age 65 and above have contributed substantially to these gains in the past 40 years. An individual reaching age 65 can now expect to live an average of 17 additional years[1] and life expectancy for older persons is expected to continue to rise into the next century.[2] An important and unresolved issue is whether the postponement of death that results from declining mortality rates will be accompanied by a similar postponement in serious morbidity.[3–6] In epidemiologic studies of aging, therefore, there are enormous potential benefits in identifying factors which not only influence longevity but also promote survival in an independent, highly functional state of health.

Rowe and Kahn have recently proposed use of the term successful aging to describe the concept that decline in organ functioning and physiologic processes are not necessarily an inherent part of aging.[7] Extending this concept for the purpose of identifying the healthy older person is not a straightforward process, however. In one of the few studies which has attempted to operationalize the concept of healthy aging in a population of older persons, Benfante, Reed and Brody considered healthy aging to be present in a subset of the Honolulu Heart Study cohort which was disease-free at baseline and had no incident chronic diseases over a 12-year follow-up period.[8]

The assessment of functional capacity can also serve as a valuable indicator of positive outcomes in aging as well as an indicator of disability. This study examines one aspect of healthy aging, namely the maintenance of very high levels of physical functioning. The study begins in middle age and examines functional status almost two decades later.

Methods

Study Population

The population used in these analyses is a subsample of a study of adults in Alameda County, California, the study design and sampling for which have been reported in detail elsewhere.[9,10] In 1965, a representative sample of adults age 20 and older (16 if ever married) was selected. In total, 6,928 individuals completed an extensive questionnaire about their health and behavioral, social and psychological aspects of their lives. Respondents were again contacted in 1974 and in 1982/83 a random 50 percent sample of 1974 respondents was contacted. In 1984, interviews were conducted with those individuals who were born prior to 1920 and who had completed the 1982/83 questionnaire.

The current analyses are limited to the cohort born between 1895 and 1919, who were age 65 to 89 at follow-up in 1984 or who died prior to that time. To be eligible for the 1984 survey, participants had to have been selected in the 50 percent random sampling of the cohort done for the 1982/83 survey. The analytic cohort for this study includes all those participating in the 1984 survey, all those dying between 1982 and 1984, and a random 50 percent sample of those dying between 1965 and 1982. This cohort consists of 841 individuals, of whom 345 (41.0 percent) died prior to 1984. Of the 496 survivors for whom an interview was completed in 1984, a proxy respondent was required for 31 (6.3 percent) due to a physical or cognitive disability.

In the 1965 baseline sample, 2,392 persons were born between 1895 and 1919. By 1974, 319 (13.3 percent) were known to have died. Of those remaining, 1,677 (80.9 percent) completed the 1974 questionnaire, 346 (16.7 percent) were located but did not respond, and 50 (2.4 percent) were not located. In 1982, 837 of the 1,677 persons responding in 1974 were randomly selected for follow-up. Between 1974 and 1982, 144 deaths occurred in this group (17.2 percent). Of the remaining 693 persons, 565 (81.5 percent) completed the questionnaire, 85 (12.3 percent) were located but did not respond, and 43 (6.2 percent) were not located. By 1984, 27 deaths occurred in the 1982 respondents (4.8 percent). Of the remaining 538 persons, 496 (92.2 percent) completed the 1984 interview, 30 (5.6 percent) were located but not successfully interviewed, and 12 (2.2 percent) were not located.

Those not located and those who were located but refused to participate were different from the cohort analyzed in this study in respect to several baseline variables. Among those born between 1895 and 1919, the group lost to follow-up tended to be younger at baseline than those successfully followed (60.2 percent of the group not located were ages 46–55, compared to 62.2 percent of the located nonrespondents and 51.6 percent of the analytic cohort). Persons lost to follow-up were more likely to be Black (Blacks comprised 19.4 percent of the group not located, 18.8 percent of the located

nonrespondents, and 14.3 percent of the analytic cohort) and had lower family incomes (those classified as having inadequate or marginal incomes at baseline comprised 36.4 percent of the group not located, 25.8 percent of the located nonrespondents, and 22.5 percent of the analytic cohort).

Outcome Status

Mortality—Deaths were ascertained through a computer-matching procedure with the California Death Registry.[11,12] Additionally, extensive in-state and out-of-state tracing was done in 1974 and 1982 for participants not responding to questionnaires.[9] For previously unascertained deaths which were reported by next-of-kin or others at the time of the 1984 survey, death certificates were requested for confirmation.

Physical Functioning—The 1984 interview contained an extensive section on physical functioning and disability, including basic activities of daily living, instrumental activities of daily living (doing housework and shopping), and more vigorous physical functioning (difficult household tasks, exercise and recreational activities). To assess the full spectrum of functioning and identify those in the cohort functioning at the highest levels, a comprehensive, summative scale was constructed. Selection of appropriate questionnaire items for this scale was accomplished by entering variables representing all items related to physical functioning into a principal factor analysis using oblique rotation.[13,14] A large number of the items loaded on the first two factors (see Appendix), which were the only factors with eigenvalues greater than 1.

Scales of basic functioning and exercise were created using items loading on the first and second factors, respectively. All items in the basic function and exercise scales were then combined to create a summary scale of functioning. While these factors represent different constructs, the scales were combined because of the underlying correlation of the two factors (reference axis correlation = .33) and because of the clear hierarchical relationship of these scales. None of those with poor scores on the basic function scale had high scores on the exercise scale while those with high scores on the exercise scale all had very high scores on the basic function scale. Cronbach's alpha was .90 for the combined scale. The distribution of scores on the combined scale is shown in Figure 1. Scores on this scale ranged from 0 to 92, with a median of 72, a mean of 68.5 and a standard deviation of 15.0. Those scores of 80 and above represent the top quintile of scores. Individuals in this group are classified as having high functioning for the purpose of the analyses to be presented here.

Baseline Variables

Data on demographic factors, chronic conditions, and health-related practices examined in these analyses were obtained from responses to the baseline 1965 questionnaire. Health-related practices examined in these analyses were those previously demonstrated in the Alameda County Study to be associated with increased probability of survival in younger[9] and older[15] persons.

Because not all participants began the study in 1965 with the same level of physical functioning, it was necessary in multivariate analyses to adjust for baseline functional status. Ideally, the same scale used in 1984 would be used to assess 1965 functional status, with this scale score being entered as an independent variable in all analyses. However, the variables making up the 1984 combined function scale were not all collected at baseline. For those variables which were collected in both 1965 and 1984, an abbreviated scale of functioning was empirically developed which, using 1984 data, had a .80 correlation with the full, 1984 combined

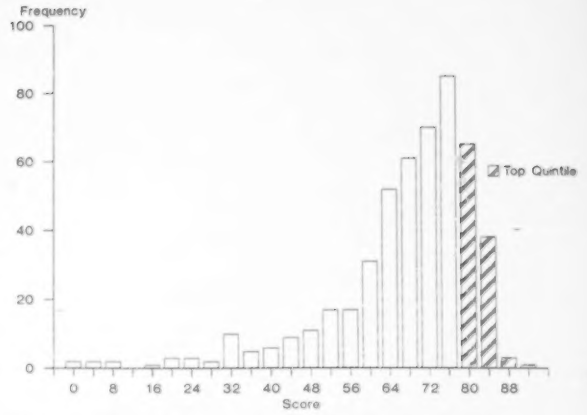

FIGURE 1—Distribution of Scores on the Combined Function Scale

function scale. In practice, this scale, using 1965 data, was entered into models as two variables, one containing basic functioning items and the other containing exercise-related items. In all models which were constructed, these 1965 variables remained highly significant predictors of high functioning in 1984. The inclusion of chronic conditions in the full models to be presented also provides an additional adjustment for health status at baseline.

Statistical Analyses

Analyses compare those in the highest quintile of scores on the combined scale of physical functioning with the remainder of their cohort, including those who died prior to follow-up. Multiple logistic analysis is used to assess the multivariate associations of baseline variables with outcome while simultaneously adjusting for age, race, sex, and baseline functional status. Parameters of the logistic function were determined using the iterative maximum-likelihood technique as described by Walker and Duncan.[16]

In the first set of analyses, the high function group is compared to all other members of the cohort, nearly half of whom had died prior to the follow-up. To investigate the possibility that significant associations found in the first set of analyses resulted simply because of the strong, well-recognized associations of many of the baseline variables with mortality, multiple logistic models using a trichotomous outcome were constructed. This allowed, in one model, for the separate analyses of associations between baseline factors and: 1) the outcome high function versus deceased, and 2) the outcome high function versus moderate to low function. These analyses were accomplished using the CATMOD procedure of SAS, modified for logistic regression.[17] This procedure uses the maximum-likelihood estimation method and yields the same results as the SAS LOGIST procedure when using a dichotomous outcome variable, but has the advantage of being applicable to polychotomous outcomes as well.

Results

Among the 841 individuals in the cohort under study, there were 496 survivors (59.0 percent) at follow-up in 1984. Of these 496 survivors, there were 107 with scores at follow-up of 80 and above on the combined function scale. This high function group comprised 12.7 percent of the original cohort of 841 persons, with low to moderate function survivors comprising 46.3 percent and decedents 41.0 percent.

Results that follow will focus on the relation of baseline states to the outcome of interest, high functioning. For those in the study cohort (including decedents) reporting no high blood pressure at baseline, 14.9 percent went on to be in the high function group 19 years later as compared to only 2.1 percent in the group reporting high blood pressure (Table 1). Those reporting no heart disease, chest pain, shortness of breath, diabetes, arthritis, joint swelling, pain or stiffness and back pain were also significantly more likely to have high functioning at follow-up than those reporting these conditions. There was a low prevalence of self-reported diabetes, stroke, and cancer at baseline, but it is of interest that no one reporting these conditions had high function at follow-up.

For demographic variables, the proportion with high function at follow-up was significantly higher for younger individuals, those not Black, those with very adequate or adequate income, and those married at baseline (Table 2). Among the health practices, non-smoking, having moderate weight, moderate alcohol consumption, and eating breakfast regularly were all significantly associated with high function at follow-up. Physical activity was not studied as an independent variable because many of the items in this scale are incorporated in the scale used to adjust for baseline functional status in multivariate models.

Models are presented in Table 3 which evaluate demographics, chronic conditions, and health practices in three separate analyses, all adjusted for age, race, sex, and baseline functional status. As in the previous results, sex is not predictive of high function. Marital status is unimportant when adjusted for other demographic variables and baseline function, while the importance of age, race, and family income remains. Of the chronic diseases, the reported absence of high blood pressure and arthritis are clear predictors of high function, with back and chest pain being somewhat less so. Being a past or never smoker and having moderate body weight are associated with high function. Those with moderate alcohol intake were 2.4 times more likely to have high function at follow-up than abstainers and 1.7 times more likely to have high function than heavy drinkers. Eating breakfast, hours of sleep, and snacking were not associated with high function in this model. The strengths of association and 95 percent confidence intervals (CI) of all variables entered into a combined model showed little difference from the individual models.

TABLE 1—Percent of Cohort (including decedents) with High Function at Follow-up According to Baseline Chronic Conditions: Alameda County Study

Chronic conditions (past 12 months)		
High blood pressure	No	14.9
	Yes	2.1
Heart disease	No	13.5
	Yes	1.9
Chest pain	No	13.9
	Yes	4.9
Shortness of breath	No	13.8
	Yes	5.9
Swollen ankles	No	13.5
	Yes	9.2
Leg cramps	No	13.4
	Yes	10.3
Stroke	No	12.9
	Yes	0.0
Bronchitis	No	12.6
	Yes	15.1
Asthma	No	12.7

TABLE 2—Percent of Cohort (including decedents) with High Function at Follow-up According to Baseline Demographic Characteristics and Health Practices: Alameda County Study

Demographic Characteristics		
Age (Baseline/Follow-up)	46–49 / 65–68	20.9
	50–59 / 69–68	15.0
	60–70 / 79–89	4.1
Sex	Male	13.9
	Female	11.7
Race	Not Black	14.3
	Black	3.3
Family Income	Very adequate-adequate*	16.2
	Marginal-inadequate	2.8
Current Marital Status	Married	14.6
	Not married	6.3
Health Practices		
Smoking	Past-Never	15.6
	Current	8.6
Relative Weight	Moderate**	14.4
	Other	6.3
Alcohol Consumption (drinks month)	None	7.0
	1–60	15.1
	>60	11.6
Eating breakfast	Regularly	14.1
	Sometimes-rarely	7.7
Hours of Sleep Per Night	7–8	13.5
	<7 or >8	10.2
Snacking	Rarely-never	14.2
	Sometimes-always	12.1

*Total household income adjusted for household size and scored in comparison to federal standards for 1965.

**Weight within 10% under and 30% over ideal weight according to Metropolitan Life Insurance 1959 standards.

Table 4, based on the trichotomous logistic model, demonstrates the association of baseline variables with three levels of outcome in 1984: high function, low to moderate function, and deceased. For example, those with no high blood pressure at baseline are 6.7 times more likely to end up in the high function group as in the deceased group and 4.1 times more likely to be in the high function group at follow-up compared to the low to moderate function group. Variables shown to be predictors of high function in previous models continue to be predictors of high function when compared both with dying during follow-up and with low to moderate function at follow-up.

Discussion

We used physical functioning as a measure of outcome, a departure from the usual disease-specific outcome in epidemiologic studies. There are numerous theoretical and practical advantages in characterizing older persons according to their level of functioning.[18] While it is certainly desirable to age with no chronic diseases, it can be problematic to characterize healthy aging according to diagnosed diseases. How important or severe must a disease be to remove someone from the healthy aging group? How intensively must we search for disease in order to declare someone disease-free? It is common for individuals who have chronic diseases but who are well compensated to live long, active, and vigorous lives, an outcome to which we all aspire. It is this outcome which is addressed in these analyses.

TABLE 3—Multiple Logistic Models Showing Association between Demographic Characteristics, Chronic Conditions and Health Practices and High Function at 19 Years: Alameda County Study

		Odds Ratio (95% CI) Demographic Model*	*Odds Ratio (95% CI)** Combined Model*
Age (10 years)	Younger/Older	2.3 (1.6, 3.5)	2.9 (1.9, 4.6)
Sex	Male/Female	1.2 (0.7, 1.9)	1.2 (0.7, 2.0)
Race	Not-black/Black	3.4 (1.2, 9.8)	2.9 (1.0, 8.7)
Family Income	Very adequate- adequate/ Marginal-inadequate	4.0 (1.5, 10.8)	4.0 (1.4, 11.2)
Current Marital Status	Married/Not married	1.3 (0.6, 2.7)	
		Chronic Condition Model	
High Blood Pressure	No/Yes	4.9 (1.4, 16.7)	4.3 (1.2, 15.1)
Heart Disease	No/Yes	1.1 (0.1, 10.2)	
Chest Pain	No/Yes	2.3 (0.7, 7.5)	
Shortness of Breath	No/Yes	1.1 (0.5, 2.8)	
Arthritis	No/Yes	2.6 (1.1, 6.0)	2.8 (1.3, 6.0)

Snacking	Rarely-never/ Sometimes-always	1.3 (0.8, 2.1)	

*Demographic, chronic condition and health practices models: odds ratios adjusted for age, race, sex, baseline functional status and all variables in the model.

**Combined model: odds ratios adjusted for baseline functional status and all variables in the model.

In choosing an outcome of functioning rather than disease status, it is important to recognize that predictors of functional status identified in this study have their influence on function through specific diseases as well as patterns of accommodation and adaptation to these diseases. However, there are important gaps in our understanding of these pathways from disease to disability in older persons.[19] Using functioning as an outcome measure does not deny the importance of these pathways, it simply uses function as an overall measure of the impact in the older person of multiple diseases, conditions, and environmental influences.

The outcome measure in this study was a summative scale created from a large group of questionnaire items representing activities with a wide spectrum of difficulty. It was created to identify participants who were not only non-disabled but were also functioning at a high level. Nevertheless, it has a number of limitations. It assesses only physical functioning and does not take into account the domains of cognitive or psychological functioning directly. Many of the items querying activities of daily living and more difficult tasks have a large cognitive component, however, and it is likely that an individual with moderate to severe dementia would have difficulty with at least some of these activities and not score in the top quintile. The distribution of scores on this scale was unimodal, so the classification of the top quintile as representing high function was somewhat arbitrary. Scores on a summative scale, as opposed to a hierarchical scale, can be obtained in a number of different ways and it can be difficult to interpret what a particular score means. However, the construction of the scale as it was done here allows for a good characterization of those classified as having high function. To obtain a score in the top quintile, individuals had perfect or near perfect scores on the basic function component of the combined scale and reported engaging in at least some of the more vigorous activities on the exercise component.

The difficulty in tapping the high end of the functional spectrum using questionnaire items may have led to misclassification of individuals on the outcome measure used here. Those with no opportunity or inclination to engage in more vigorous activities, but who might have the capacity to perform them, would have scores below the top quintile and would not be classified as having high functioning. This potential misclassification could be a source of bias affecting our findings that both income and race are strongly associated with high function. To evaluate this, an analysis was performed using the basic function scale alone as the outcome. Employing this scale as a continuous variable and studying survivors, both income and race were found to be strongly associated with this outcome, even after adjusting for all other significant variables in a multiple linear regression model.

A number of other factors known to be associated with all-cause mortality and specific diseases were demonstrated in this study to be predictive of high function. These include smoking status, relative weight, alcohol consumption, and blood pressure. Physical activity has traditionally been one of the seven health behaviors studied in the Alameda County cohort, but it cannot be studied here as a predictive variable because it is part of both the outcome variable and the baseline adjustment variable. In all multivariate models, the baseline exercise variable is significantly associated with high function at outcome. While it is not correct to infer that it is causally related to high functioning, its association with high functioning offers evidence that those with high levels of physical activity at baseline continue to have high physical activity at follow-up. Arthritis and back pain—factors usually associated with disability but not mortality—remain significant predictors of high function after adjustment for many other chronic conditions, demographics, and health practices. Interestingly, in the logistic model with a trichotomous outcome, the absence of arthritis and back pain predict survival with high function versus mortality as well as

TABLE 4—Multiple Logistic Models Showing Association between Demographic Characteristics, Chronic Conditions and Health Practices and 19-Year Status (High function, Low/moderate function, deceased)*

		High function vs Deceased	High function vs Low/moderate function
		Odds Ratio (95% CI)	Odds Ratio (95% CI)
Demographic Model			
Age (10 years)	Younger/Older	5.1 (3.2, 8.0)	1.5 (1.0, 2.3)
Sex	Male/Female	0.5 (0.3, 0.8)	1.2** (0.7, 1.9)
Race	Not-black/Black	4.1 (1.4, 12.4)	3.1 (1.1, 9.3)
Family Income	Very adequate-adequate/ Marginal-inadequate	4.9 (3.0, 8.2)	3.1 (1.4, 10.2)
Chronic Conditions Model			
High Blood Pressure	No/Yes	6.7 (1.9, 23.8)	4.1** (1.2, 14.1)
Arthritis	No/Yes	2.4 (1.1, 5.3)	3.0 (1.4, 6.5)

survival with high function versus low to moderate function.

An important finding in this study is that in analyses in which the high function outcome group is compared to the remainder of the cohort, sex is not a predictor of high function; the logistic analysis with trichotomous outcome suggests the reasons: females are more likely to be in the high function group when comparing this group with decedents, but among survivors males have a greater likelihood of being highly functional. Sex did not predict function at older ages because of the poorer survival in males and the poorer functional outcome in surviving females compared to surviving males. This is compatible with the findings of Katz and colleagues who found, in a cohort of persons already age 65 and older, that differences in average remaining disability-free years between males and females in different age groups were quite small and did not reflect the large differences in remaining life expectancy at these ages.[20]

There are no other prospective studies with long-term follow-up which provide data on how factors assessed in a cohort which is middle-aged at baseline predict high function when the survivors have passed age 65. In their study of factors associated with remaining disease-free in Japanese men ages 46–69 at baseline, Benfante, Reed and Brody found that systolic blood pressure, total cigarettes smoked, body mass index, and alcohol consumption measured at baseline were all inversely related to remaining disease-free at follow-up 12 years later.[8] In analyzing the effect of alcohol intake, they found the highest probability of remaining disease-free among alcohol abstainers, in contrast to our finding that moderate drinkers had a higher probability than abstainers of having high function at follow-up. Their physical activity index was not predictive of remaining disease-free.

Several studies have explored the relation of risk factors to the development of disability. Pinsky and colleagues used the Framingham Heart Study to investigate how traditional risk factors for heart disease predict disability in a subsample of survivors who remained free of diagnosed cardiovascular disease.[21] Ever having hypertension was predictive of disability in both men and women and elevated body mass index was predictive in women, but cigarette smoking was not associated with disability. Palmore studied demographic predictors of disability in a cohort followed for approximately 10 years, whose surviving members were age 72 and older at follow-up.[22] Adjusting for baseline disability, only age and a scale of physical health (measured in terms of disease presence and severity) were significant predictors of disability at follow-up. Sex, race, marital status, education, and income were not independent predictors of disability. Branch investigated incident disability in a cohort of persons age 66 and older who were followed for five years.[23] A number of health practice variables similar to those used in the Alameda County Study were evaluated. Slowed down activity in women and current or past smoking in men were the only variables predictive of disability in this study. It is of interest that the latter two studies, in which cohorts were already at older ages at baseline, found few variables predictive of disability.

One limitation of the present study is the selective loss during the follow-up period of more persons in the younger part of the study population, more Blacks, and more individuals with low family income levels. These losses are likely to bias the estimation of overall levels of physical functioning in 1984. However, specific risk estimates would be biased only if the associations of baseline risk factors with the outcome were different for those lost to follow-up and those remaining in the cohort. Because individuals who are lost to follow-up tend to have poorer outcomes than those who remain, it is likely that the inclusion in the study of those Blacks and low income individuals who were lost would have resulted in even stronger associations of race and income with functional outcome.

Findings in this study should also be interpreted in light of the potential changes in the baseline variables during the long follow-up period. In certain cases it is advantageous to measure risk factors during middle age. Assessing income at older ages may not give a valid picture of income during the pre-retirement years, so our baseline measure of income has particular advantages. However, some variables likely to change significantly after their baseline assessment may not reflect status during majority of the follow-up period. As an example, marital status as reported at baseline, which was not a significant predictor of high functioning, may not have been a good measure of marital

status during the 19 years of follow-up. In an older population such as this, many individuals married at baseline may have been widowed in the first few years of follow-up.

It is also doubtful that a single report of high blood pressure at baseline was representative of blood pressure status during the long follow-up period. Misrepresentation of blood pressure status could result from unreliable reporting, the use of antihypertensive medications, which was not assessed at baseline, the degree of blood pressure control and the development of hypertension after the baseline assessment. This type of misclassification would lead to a conservative bias in assessing the association of blood pressure with high function. Indeed, it is striking that a single question about high blood pressure asked 19 years prior to assessing function was so highly predictive of high function. These findings, along with those of Benfante and colleagues and Pinsky and colleagues, indicate that absence of hypertension may be one of the most important predictors of healthy aging. The benefits of hypertension control on cardiovascular disease are well documented.[24–26] Studies to assess how hypertension control affects overall health status and disability in older persons have not been done and would be very valuable.

As mortality rates decline and the average age at death is postponed, there will be a marked expansion in overall population morbidity levels if the onset of disease and disability is not postponed an equal or greater number of years. It is clear that in the next century the older population will survive longer and grow to unprecedented size. The findings from this study indicate the possibility that active intervention in areas which promote healthy aging might lead to an aging population which retains high levels of function for a longer proportion of their lives and is therefore less dependent on their families and the health care system.

APPENDIX

This list summarizes items loading on factors 1 and 2. The first factor contains items which mostly relate to basic functioning, that is, activities necessary in day-to-day life. Loading heavily on the second factor were items related to exercise. Miscellaneous items loaded on a third factor and were dropped from further scale construction. The grouping pattern of items on the first two factors was understandable and in general reflected what one might have constructed *a priori*. These two scales were therefore retained and items were given equal weighting in the creation of summary measures.

Factor 1—Basic Function Scale

Activities of daily living: bathing, grooming, dressing, eating, transferring from bed to chair, using the toilet
Walking across a small room
Climbing stairs
Walking one-half mile
Pushing or pulling a large object
Stooping, crouching, kneeling
Lifting and carrying weights over 10 pounds
Gardening
Meal preparation
Heavy housework
Difficulty getting places
Shopping

Factor 2—Exercise Scale

Any sports exercise
Walking for exercise

Is Early Natural Menopause a Biologic Marker of Health and Aging?

David A. Snowdon, PhD, MPH, Robert L. Kane, MD, W. Lawrence Beeson, MSPH, Gregory L. Burke, MD, J. Michael Sprafka, PhD, John Potter, MD, PhD, Hiroyasu Iso, MD, David R. Jacobs, Jr., PhD, and Roland L. Phillips, MD, DrPH*

Abstract: The relation between age at natural menopause and all-cause mortality was investigated in a sample of 5,287 White women, ages 55 to 100 years, naturally-postmenopausal, Seventh-day Adventists who had completed mailed questionnaires in 1976. The age-adjusted odds ratio of death during 1976–82 in women with natural menopause before age 40 was 1.95 (95% confidence interval = 1.24, 3.07), compared to the reference group of women reporting natural menopause at ages 50 to 54. Corresponding odds ratios of death were 1.39 (95% CI = 1.06, 1.81) for natural menopause at ages 40 to 44, and 1.03 (95% CI = 0.84, 1.25) for natural menopause at ages 45 to 49. Among 3,166 White, 55- to 100-year-old, surgically-postmenopausal, Adventist women, there was no relation between age at surgical menopause and mortality. Logistic regression analyses indicated that findings from this study were apparently not due to confounding by smoking, over- or underweight, reproductive history, or replacement estrogen use. (*Am J Public Health* 1989; 79: 709–714.)

Introduction

Advancing age is associated with substantial adverse changes in many physiologic characteristics,[1–10] increases in morbidity,[11] decreases in the capacity for self care at older ages,[12] and increases in mortality.[13] Reproductive functions also show a strong and predictable change with advancing adult age. As age increases between age 30 and menopause, women experience more anovulatory cycles, infertility, chromosomal abnormalities related to oogenesis, and spontaneous abortions.[14] While other organs and physiologic systems usually decline in performance yet continue to function with advancing age, the ovaries decline and essentially cease functioning at menopause.

Several animal species, such as some salmon, mollusk, spiders, and octupus die within a predictable time after mating or reproducing.[15] While these may be extreme examples, they suggest that neural and endocrine mechanisms play a role in determining length of life in some animals. Furthermore, environmental factors that affect the health and aging of reproductive organs also might simultaneously affect other organs and tissues. For example, cigarette smoking adversely affects the function of the reproductive system[16–18] as well as the function of the cardiovascular system, in addition to reducing life expectancy.[18,19]

Based on these considerations, we hypothesized that age at natural menopause would be a biologic marker of the general health and aging state of the individual. Because mortality is an indicator of health and aging, we tested the hypothesis that age at natural menopause is negatively associated with all-cause mortality.

Methods

Study Population and Questionnaires

In 1974, Seventh-day Adventist households in California were identified from church records and a Census Questionnaire mailed to virtually every household. A total of 25,186 White Adventist women 25 to 100 years of age, not of Hispanic origin, were identified by the census. In 1976, Adventists identified in the previous census were mailed another questionnaire called the Lifestyle Questionnaire. Of the 25,186 women originally identified in the census, 19,586 (78 percent) completed the Lifestyle Questionnaire. Variables from the Lifestyle Questionnaire used in the multivariate analysis and our method of coding are described in the Appendix.

Of the 19,586 women 25 to 100 years of age who completed the Lifestyle Questionnaire, 10,198 were 55 to 100 years of age. Of these women, 5,287 (51.8 percent) reported they were naturally-postmenopausal, 3,166 (31.0 percent) surgically-postmenopausal, 75 (0.7 percent) pre-menopausal, and 1,670 (16.4 percent) were either unknown for type or age at menopause or had an implausible age at menopause (i.e., age at menopause was greater than 64 or greater than the subject's age). While there is no generally accepted normal range for age at menopause,[20] age 64 was used in this study as the last acceptable year. Thus, the study population for this report was the 5,287 naturally- and 3,166 surgically-postmenopausal women who were 55 to 100 years of age at the start of the study (i.e., restricted to those ages where virtually all women were postmenopausal).

Mortality Surveillance

Mortality data in this report cover the time between the completion of the Lifestyle Questionnaire in 1976 and the end of the follow-up on December 31, 1982. Of the 19,586 women who completed the Lifestyle Questionnaire, 17,447 (89.1 percent) were known to be alive when the follow-up ended because they completed a mailed questionnaire in 1983, a death certificate indicated they died after 1982, or a personal contact by phone indicated they were alive in 1983. A total of 1,439 (7.3 percent) of the 19,586 women died during the 1976–82 time period. All deaths were confirmed by death certificates. Vital status at the end of follow-up in 1982 could not be determined for 700 (3.6 percent) of the 19,586 women. Data for these 700 women were compared to data on the computerized California state death certificate files for 1976–82 and the National Death Index for 1979–83 but no positive matches with an accompanying death certificate were located. Thus, these 700 women were treated as "alive" in the data analyses.

Statistical Analyses

Prior to analyses, age at menopause was categorized into five groups (i.e., less than 40 years, 40 to 44, 45 to 49, 50 to 54, and 55 to 64) with those having menopause at ages 50 to 54 as the reference category (for all odds ratios). Age-specific odds ratios and their confidence intervals were estimated by methods described by Mantel and Haenszel.[21] Age-adjusted odds ratios and their precision-based confidence intervals were estimated by methods for stratified data described by Woolf and Haldane.[22,23] Odds ratios adjusted for other variables were estimated by a maximum likelihood logistic regression model.[24]

Results

Age at Natural Menopause

These analyses were based on 5,287 naturally-postmenopausal women who were 55 to 100 years of age at the start of the study in 1976. The mean age at natural menopause in these women was 49.21 (SE = 9.70); mode = 50, median = 50, 25th percentile = 46, and 75th percentile = 52.

Of these 5,287 women, 772 died during the study (i.e., 1976–82), 4,356 survived to the end of the study, and 159 were presumed to be alive at the end of the study (i.e., we lost contact with these subjects sometime during the study). However, there was no difference in the age at natural menopause between the 4,356 women known to have survived and the 159 presumed to have survived to the end of the study. Age-specific Spearman rank correlations ranged from −0.01 to 0.07 for the association between age at natural menopause and "living status" (i.e., 0 = presumed alive; 1 = known alive).

Age-specific results (Table 1) indicated that the odds ratio of death decreased with increasing age at natural menopause until age 55. This negative association between age at natural menopause and death was evident within each age group except women 85 years of age and older in 1976. Other age-specific results (Figure 1) also indicated similar negative associations between age at natural menopause and the probability of death (denominator based on counts of people) and the rate of death (denominator based on person-years of observation). Because of these findings, all other analyses were limited to odds ratios (based on counts of people).

To control for potential confounders, logistic regression analyses were done using four models which adjusted for (I)

	40–44	1.39 (1.06, 1.81)	537	105	3378
	45–49	1.03 (0.84, 1.25)	1532	230	9636
	50–54	1.00	2314	300	14555
	55+	1.11 (0.85, 1.46)	778	103	4894
		trend p = 0.02[p = 0.002]			

[a]The reference category for the odds ratio was the group of women that became naturally-postmenopausal at ages 50 to 54.

[b]Women who survived to the end of the study had 6.29 person-years of observation (i.e., the years that elapsed between the beginning of the study on September 15, 1976 and the end of the study on December 31, 1982). For women who died during the study, person-years corresponded to the years that elapsed between the beginning of the study and the date of death.

[c]Trend p refers to the two-tailed p-value for the test of the linear trend in odds ratios across all "age at menopause" groups. The value in brackets refers to the trend p-value across all "age at menopause" groups except the "55+ age at menopause" group.

[d]Age-adjusted by stratification.

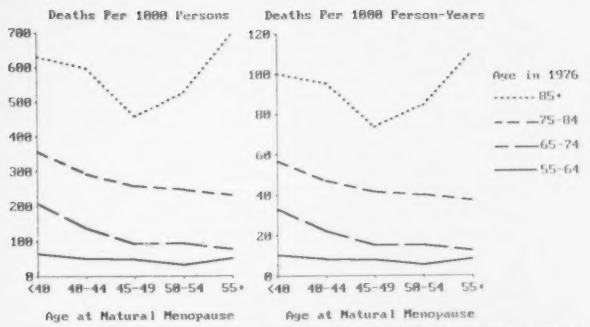

FIGURE 1—Age at Natural Menopause and the Probability and Rate of Death for 5,287 California Seventh-day Adventists, 1976–82

age in 1976, (II) age in 1976 and lifestyle-related factors (III) age in 1976, lifestyle-related factors, and reproductive-related factors, and (IV) age in 1976, lifestyle- and reproductive-related factors, and replacement estrogen use. Variables included in these models and our method of coding are described in the Appendix. Odds ratios of death for different age at natural menopause groups were essentially identical when these four types of analyses were done separately (Table 2). Since the type of model used in the regression analyses did not materially affect these and other odds ratios, all subsequent multivariate-adjusted findings refer to the results from Model IV. Model IV results indicated that women with natural menopause before age 40 had a multivariate-adjusted odds ratio of death of 3.03 (95% CI = 1.62, 5.65), compared to women with natural menopause at ages 50 to 54. The odds ratio of death also decreased in a stepwise fashion with increasing age at natural menopause until age 55.

These odds ratios (Table 2) were larger than those from the age-adjusted stratified analyses (Table 1) because the regression was limited to 3,334 women who had known values for all the variables included in the logistic model rather than the 5,287 women who only had known values for age in 1976 and menopausal status. This increase in the odds ratios appeared to be due, in part, to a selective loss of older subjects: 74 percent (1415/1918) of the 55 to 64 year-old age group were in both analyses, compared to 60 percent (1096/1830) in the 65 to 74 year-old age group, 52 percent (596/1145) in the 75 to 84 year-old age group, and 58 percent (227/394) in the group that was 85 years of age and older. Within each of these age groups, however, women with natural menopause before age 40 had the highest multivariate-adjusted odds ratio of death (ranging from 1.56 among women who were 75 to 84 years of age in 1976 to 8.49 among women who were 85 years of age and older).

In separate analyses to estimate possible effects of replacement estrogens, the odds ratio of death for women who were naturally-postmenopausal before age 40 was 3.33 (95% CI = 1.14, 9.72) within the group that ever used replacement estrogens and 2.91 (95% CI = 1.33, 6.36) within the group that never used replacement estrogens (compared to the reference group who were naturally-postmenopausal at age 50 to 54). Among all naturally-postmenopausal women, the multivariate-adjusted odds ratio of death was 1.13 (95% CI = 0.88, 1.45) for those who ever used replacement estrogens compared to those who never used replacement

TABLE 2—Age at Natural Menopause and the Age-adjusted and Multivariate-adjusted Odds Ratio of Death in 3,334 California Seventh-day Adventists, 1976–82[a]

		40–44	1.51 (1.04, 2.19)
		45–49	1.07 (0.81, 1.42)
		50–54	1.00
		55+	1.41 (1.00, 1.99)
IV	Age in 1976; Lifestyle Factors; Reproductive Factors; Replacement Estrogens	<40	3.03 (1.62, 5.65)
		40–44	1.51 (1.04, 2.20)
		45–49	1.07 (0.81, 1.42)
		50–54	1.00
		55+	1.40 (0.99, 1.97)

[a]There were 5,287 women with known responses to the menstrual-related questions on the questionnaire. Of these women, 3,334 had known responses to all the lifestyle- and reproductive-related variables included in the multivariate-adjusted analyses (i.e., logistic regression).

[b]For the 3,334 women (known for all the variables included in the multivariate analyses), the age-adjusted (by stratification) odds ratio of death was 3.34 (95% CI = 1.79, 6.21) for natural menopause before age 40, 1.58 (95% CI = 1.08, 2.30) for menopause at ages 40 to 44, 1.12 (95% CI = 0.86, 1.47) for menopause at ages 45 to 49, 1.00 for menopause at ages 50 to 54, and 1.41 (95% CI = 0.99, 2.02) for natural menopause at ages 55 and older.

[c]Lifestyle and reproductive variables are descrioed in the Appendix.

estrogens. Within each age at natural menopause group, ever use of replacement estrogens was associated with only a slight elevation of the odds ratio. Thus, replacement estrogen use did not weaken the association between age at natural menopause and mortality.

Age-adjusted and multivariate-adjusted cause-specific analyses were done in order to determine which of the major causes of death might be responsible for the relationship between age at natural menopause and all-cause mortality (e.g., the multivariate-adjusted analyses on heart disease had the dependent variable equal to "1" if the person died of coronary heart disease and "0" if the person was alive at the end of the study or died of some other cause). Coronary heart disease and stroke mortality each had elevated age- and multivariate-adjusted odds ratios associated with early natural menopause, while the multivariate-adjusted odds of cancer mortality was slightly lower in women with early natural menopause (Tables 3 and 4). Early natural menopause was associated with an excess mortality due to all other causes of death combined. Separate analyses on injuries and other specific causes of death were not performed because there were not enough deaths due to these causes.

Age at Surgical Menopause

Age at surgical menopause was weakly and inconsistently positively associated with all-cause mortality in the age-adjusted analysis on 3,166 women, and the multivariate-adjusted analyses on 2,096 women (who had known responses to all the variables included in the multivariate analyses). The multivariate-adjusted odds ratio of death was 0.75 (95% CI = 0.47, 1.20) in women who were surgically-postmenopausal before age 40, 0.84 (95% CI = 0.52, 1.35) in those surgically-postmenopausal at ages 40 to 44, 0.77 (95% CI = 0.47, 1.28) in those postmenopausal at ages 45 to 49, and 0.89 (95% CI = 0.32, 2.43) in those postmenopausal at age 55 and older, when compared to those surgically-postmenopausal at ages 50 to 54. Age at surgical menopause was unrelated to mortality due to coronary heart disease, stroke, cancer, and all other causes combined.

Replacement estrogen use was associated with a slight decrease in the risk of all-cause mortality in the surgically-postmenopausal women. Among all surgically-postmenopausal women, the multivariate-adjusted odds ratio of death was 0.80 (95% CI = 0.56, 1.14) for those who ever used replacement estrogens compared to those who never used replacement estrogens. These odds ratios for ever use of replacement estrogens were lowest among women with early surgical menopause. For example, within the group that were surgically-postmenopausal before age 40, the multivariate-adjusted odds ratio of death for ever use of replacement estrogens was 0.57 (95% CI = 0.29, 1.10), compared to never use of replacement estrogens.

Discussion

Findings from this study suggest that early age at natural menopause is associated with a substantial excess mortality. In addition, women who report natural menopause at ages 55

[a]See Table 2 for explanation.
[b]Cause of death is the underlying cause of death from the death certificate that was coded by the California State nosologist. Cause-of-death codes from the International Classification of Disease, version nine, were used to classify deaths by major cause; coronary heart disease = codes 410–414, stroke = 430–438, cancer = 140–239, and all other causes of death combined = all other codes.
[c]All results in this table have been age-adjusted by stratification. The reference category for the odds ratio was the group of women that became naturally-postmenopausal at ages 50 to 54.
[d]See footnote "c" in Table 1.

[c]These logistic regression analyses adjusted for age in 1976, replacement estrogen use, and the lifestyle- and reproductive-related variables described in the Appendix.

and older may have a slightly higher risk of death than women with natural menopause at ages 50 to 54. While we have no data to test the hypothesis directly, some of the women who reported menstrual periods at such a late age may have mistaken disease-related vaginal or uterine bleeding for normal menstrual bleeding. If this occurred, it could explain the slightly higher risk of death in these women.

Our study used self-reports of type of menopause and age at menopause from a mailed questionnaire. No studies have investigated the validity of self-reported age at natural menopause. However, a study of 6,591, 30- to 55-year-old nurses found that for questionnaires mailed two years apart, 95 percent of the surgically-postmenopausal women and 82 percent of the naturally-postmenopausal women reported their age at menopause within one year on both questionnaires.[25]

The possibility that our findings were due to confounding by potential correlates of age at menopause was investigated by logistic regression analyses. Controlling for self-reported cigarette smoking, over- and underweight, reproductive history, and replacement estrogen use did not materially alter our findings. Moreover, cigarette smoking is not an important issue in this study population because at the beginning of our study only 1.5 percent of the women were current smokers and 13.2 percent former smokers.

While our findings seem solid, it would be reassuring to find evidence of these associations in other populations. Other studies have investigated only the relationships between age at menopause and the risk of specific diseases. Age at natural or surgical menopause was positively associated with the risk of breast cancer in several studies.[26] Age at menopause (both surgical and natural combined), however, has been negatively associated with osteoporosis.[27,28] Results from two small Swedish studies also suggest that age at menopause is negatively associated with the risk of developing myocardial infarction.[29,30] Among 45- to 54-year-old women in the Framingham Study, naturally- and surgically-postmenopausal women both had 2.7 times the incidence of coronary heart disease (including angina pectoris) compared to pre-menopausal women of the same age.[31]

We found no evidence that estrogen depletion was related to mortality. Replacement estrogen use was not associated with a reduction in mortality in women with early or late age at natural menopause. In spite of the "estrogen depletion" in the group of surgically-postmenopausal women in our study, age at menopause was unrelated to mortality in these women.

Premature natural menopause may be related to mortality because of aging-related physiologic processes that are associated with early natural menopause. The function of the ovaries throughout life and the start and permanent cessation of menstruation are highly dependent on age. The average number of ovarian germ cells or oocytes present in human females appears to be greatest around the fifth or sixth month of fetal development.[32] Thereafter, the number of surviving oocytes regularly declines pre- and post-natally until menopause is apparently precipitated by an insufficient number of surviving oocytes and follicles.[14] This involution of the ovaries would appear to be a natural consequence of aging (as opposed to disease), particularly since the average age at menopause appears to have been remarkably consistent in western countries throughout the last three decades.[33]

Ovarian aging, as reflected by age at natural menopause, may be highly correlated to the aging of other tissues and to the mortality produced by aging (i.e., the increase in mortality with age that would probably inevitably occur even in the absence of disease). Further investigation is needed to pinpoint whether age at natural menopause is only related to a few diseases, or whether it is a marker of multiple aspects of health and aging.

APPENDIX

Variables from the Lifestyle Questionnaire

The Lifestyle Questionnaire contained questions on food and beverage consumption, physical activity, smoking, occupation, psychosocial characteristics, and medical history. The questionnaire also contained questions on whether the subject's menstrual periods had permanently stopped, why they stopped, and the age of the subject when they stopped. Each participant's responses to six questions on the Lifestyle Questionnaire also were used to create a summary index of participation in church activities (e.g., attending church services, holding church office, and attending church social events). Variables used in the regression models (and our method of coding) are described below:

Age In 1976

1. chronologic age (as one continuous term).

Lifestyle Factors

1. cigarette smoking status in 1976 (as a dummy, binary, term indicating whether they currently smoked),
2. pack-years of cigarettes smoked in the past (as one continuous term),
3. Quetelets Index (using dummy terms for each of the top three quartiles of the "weight in kilograms/height in meters squared" distribution with the bottom quartile as the reference),
4. education (as one ordinal term),
5. marital status (as one binary term indicated whether the women had ever married),
6. age at joining the Adventist Church (as one ordinal term), and

7. index of participation in church activities (as one ordinal term).

Reproductive Factors

1. age at first live birth (using dummy terms for less than 25 years of age, 25 to 30, and 31 or older, with the group of women with no live births serving as the reference),
2. number of live births (as one continuous term),
3. combined number of miscarriages and stillbirths (as one continuous term),
4. age at menopause (using dummy terms for less than 40 years of age, 40 to 44, 45 to 49, and 55 and older, with the group of women with menopause at ages 50 to 54 serving as the reference).

Replacement Estrogens

1. replacement estrogen use (as a binary term indicating whether the subject had ever or never used replacement estrogens).

ACKNOWLEDGMENTS

Data that were analyzed for this report are from a study started in 1974 by Roland Phillips. The study was directed by Roland Phillips until his death on March 8, 1987. The authors wish to recognize the assistance of Del Marie Rysavy, Howard Liang, Gary Fraser, Paul Mills, and Mary Alice Schumacher. This work was supported by a grant from the National Cancer Institute, grant number 5R01CA14703-14.

APHA Job Placement Service

A Job Placement Service, facilitating the employment process for both applicants and recruiters, will be conducted during the 117th Annual Meeting of the American Public Health Association in Chicago, Oct. 22–26, 1989. Employers may list job vacancies and review resumes of candidates. Job applicants in turn, may submit resumes and review position descriptions. On-site interviews will be arranged at the employer's request. Those who are unable to attend the Annual Meeting, may purchase binders of available positions or applicant resumes. Registration forms will appear in the July and August 1989 issues of the Journal.

The Relation of Body Fat Distribution, as Assessed by Six Girth Measurements, to Diabetes Mellitus in Women

David S. Freedman, PhD, and Alfred A. Rimm, PhD

Abstract: Independently of the amount of adipose tissue, certain patterns of fat distribution increase the risk of non-insulin-dependent diabetes. Although the ratio of waist to hip (WHR) circumferences has been consistently related to diabetes mellitus, it is possible that only two measures do not completely characterize fat topography. The current study, therefore, examines the cross-sectional relation of six girths (waist, hip, neck, bust, wrist, and ankle) to diabetes mellitus in 43,595 women. As compared with non-diabetics, Quetelet index (kg/m^2) and all circumferences were elevated among diabetics. Stratified analyses showed that WHR, and waist, neck, and bust girths were consistently related to diabetes independently of the degree of overweight. As estimated from a logistic regression model that simultaneously controlled for age and all anthropometric variables, the prevalence of diabetes mellitus was positively related to Quetelet index, and to the waist, bust, and neck girths, with odds ratios (ORs) ranging from 1.4 to 2.6. However, diabetes was *inversely* related to hip (OR = 0.61) and ankle (OR = 0.73) girths; $p < 0.005$ for each association. Although cross-sectional in nature, these results suggest that an adverse body fat distribution is not limited to the abdominal region, but that a relative preponderance of adipose tissue in various regions of the upper body is associated with diabetes mellitus in women. (*Am J Public Health* 1989; 79:715–720.)

Introduction

Obesity is associated with numerous metabolic disorders and is often the primary cause of non-insulin-dependent diabetes.[1] Although obesity is a heterogenous entity,[2] systematic methods to characterize the distribution of body fat have long been in existence.[3] Vague, however, was the first to observe that, even at the same degree of overweight, women with a male (android) pattern of upper-body obesity have a greater prevalence of diabetes and atherosclerosis than do women with gynecoid obesity.[4] Android obesity was initially characterized by: 1) more subcutaneous fat at the nape of the neck than at the sacrum; and 2) a higher ratio of fat to muscle in the arm than in the thigh.[4,5]

However, other patterns of fat distribution have also been related to diabetes mellitus. Feldman, *et al*,[6] showed that female diabetics have a relative excess of subcutaneous fat in the subscapular, chest, and waist regions as compared to the triceps, and others[7–10] have confirmed the importance of a truncal fat distribution. Another body fat pattern, emphasizing abdominal obesity, has been defined by using the ratio of waist to hip (WHR)[11] or thigh[12] circumferences. An elevated WHR is related to the prevalence[13] and incidence[14] of diabetes mellitus, and to various metabolic complications.[15] Although additional validation studies are needed, both skinfold thickness and circumference measurements can be used to characterize the distribution of adipose tissue.[16]

Although other body fat patterns have been identified, several of these involve combinations of localized fat deposits, and are difficult to classify.[17–19] Because recent studies of diabetes mellitus have typically used only two skinfold or girth measurements to characterize body fat topography,[6,10,11,13–15] important aspects of fat patterning may have been overlooked. For example, WHR is only moderately correlated (r = 0.5 to 0.8) with Vague's android obesity.[5,20]

It is therefore possible that an adverse distribution of body fat is not restricted to the abdominal region (as assessed by WHR) but may encompass other areas in the upper body. The objective of the current study is to determine whether, in addition to the waist and hip girths, other circumference measurements are associated with diabetes mellitus in women independently of the degree of overweight.

Materials and Methods

Population

In 1969, approximately 125,000 questionnaires were distributed throughout the United States and Canada to local chapters of the Take Off Pounds Sensibly (TOPS) Club, an organization committed to weight reduction. Previously diagnosed diabetes was ascertained in the first part of the questionnaire, which was completed at a meeting of the local chapter. In the second part, completed at home, members were asked to list their current measurements for neck, bust, waist, hip, wrist, and ankle. (Forms were returned in sealed envelopes to assure confidentiality.) A detailed description of the study population, along with the questionnaire, has been published.[21,22]

A total of 73,532 White women completed the questionnaire, and the current analyses are restricted to non-pregnant, 20- to 70-year-olds (n = 67,902). The diabetic status of 3.7 per cent (n = 2,534) could not be determined, and data concerning one or more circumferences were missing for approximately one-third of the eligible women. In order to use the same set of women in all analyses, women with missing data for diabetes or any girth measurement were excluded. The sample size for all analyses was 43,595.

Of the women excluded because of missing girth measurements, wrist circumference was most likely to be incomplete (n = 21,277), whereas bust circumference was least likely to be missing (n = 9,059). Analyses were performed to determine whether these exclusions could have biased the results, and it was found that response was not related to any of the anthropometric measures nor to diabetes mellitus. For example, 4.7 per cent of the excluded women were diabetic, and their mean WHR was 0.04 higher than the mean WHR among non-diabetics. Comparable values were 4.5 per cent and 0.04 among women who were included in the study (see Table 1).

TABLE 1—Comparison of Selected Characteristics between Nondiabetics and Diabetics

Characteristics	Percentiles:	Nondiabetics (n = 41,613)				Diabetics (n = 1,982)				t-Statistic[a]
		25	50	(mean)	75	25	50	(mean)	75	
Age (years)		31	39	(40)	48	38	46	(46)	54	21.7
Weight (kg)		66	74	(78)	86	73	85	(87)	98	21.3
Height (cm)		157	163	(163)	168	157	163	(163)	168	3.6
Quetelet Index (kg/m^2)		25.6	28.8	(30.0)	33.0	28.4	32.8	(33.8)	38.0	23.1
Circumferences										
Waist (cm)		74	81	(83)	89	81	91	(93)	102	29.2
WHR		0.72	0.76	(0.76)	0.80	0.76	0.80	(0.80)	0.84	24.8
Bust (cm)		94	99	(100)	107	97	107	(107)	114	24.6
Neck (cm)		33	36	(35)	36	33	36	(36)	38	21.6
Hip (cm)		102	107	(109)	114	104	114	(116)	124	19.4
Wrist (cm)		15	18	(17)	18	15	18	(17)	18	12.9
Ankle (cm)		20	23	(23)	25	23	23	(24)	25	8.0

[a]A t-statistic ≥ 3.3 indicates that the mean values are significantly different at the 0.001 level; a value ≥ 3.9 indicates statistical significance at the 0.00001 level.

Quetelet index (kg/m^2) was used as a measure of overweight.[23] Although weight was highly correlated with Quetelet index (r = 0.93), a cross-tabulation of quintiles of weight and Quetelet index indicated that Quetelet index (but not weight) was independently associated with the prevalence of diabetes. Furthermore, Quetelet index was strongly (r > 0.99) associated with relative weight, and was only weakly related (r = −0.08) to height. Mean values of relative weight across quintiles of Quetelet index were: 102, 114, 126, 140, and 172 per cent.

Disease Status

Diabetic status was determined from each subject's response to the question, "Has a doctor ever said that you have diabetes?"; 4.5 per cent (n = 1,982) responded "yes". Although these self-reported histories were not verified, agreement between self-reported gallbladder disease and physician's records has been examined: there was 13 per cent overreporting and 1.6 per cent underreporting by TOPS members.[24] Although the prevalence of undiagnosed diabetes in the US population may be substantial,[25] members of TOPS are likely to be more aware of chronic, obesity-related conditions than are other persons.

Women were also asked questions concerning the duration of diabetes and insulin usage. Of the 1,982 diabetics, 350 reported that they had been diagnosed within the last year and 322 reported using insulin. Because a large proportion of insulin users are non-insulin-dependent,[26] these latter women were included in all analyses. However, analyses restricted to non-insulin-using diabetics yielded similar results.

Statistical Analyses

Distributions of the anthropometric variables were non-normal. Neck, wrist, and ankle circumferences each had a high kurtosis, indicating a sharp peak with long tails; for example, 91 per cent of the women reported a wrist girth of six or seven inches. In contrast, distributions of Quetelet index and the truncal circumferences (bust, waist, and hip) were relatively flat. Both parametric and non-parametric tests were used in several analyses, but because of the large sample size, results were very similar.

Mean levels (and selected percentiles) of the anthropometric variables were first contrasted between non-diabetics and diabetics. Interrelationships among the circumferences were examined using Pearson correlation coefficients, and partial correlations were used to determine whether associations existed independently of the degree of overweight. Levels of Quetelet index and each girth measurement were then cross-classified, and independent increases in diabetes prevalence with each girth measure were assessed using the extended Mantel-Haenszel test for trend.[27]

Logistic regression was used to examine the relation of each girth measurement to diabetes, while simultaneously controlling for all other variables. To avoid assumptions concerning the shape of the associations, two indicator variables (representing contrasts among tertiles) were used for each predictor variable.[28] Estimated odds ratios (ORs) represent the odds of diabetes for women in the middle (or upper) tertile of each circumference vs the odds of diabetes for women in the lowest tertile.

Results

Mean levels and selected percentiles of age and the anthropometric variables are shown in Table 1. Diabetics were substantially older and heavier, with a mean Quetelet index that was 3.8 kg/m^2 higher than among non-diabetics. In addition, all circumference measures were larger among diabetics, with waist girth showing the largest mean difference (9.4 cm). In contrast, differences in ankle and wrist girths between the two groups were relatively small. Although the mean level of WHR among diabetes was only 0.04 higher than among non-diabetics, this ratio showed relatively little variability: the 25th and 75th percentiles among non-diabetics were 0.72 and 0.80, respectively.

Although diabetics had larger circumferences at all sites, assessing the independent relation of each girth measurement to diabetes was complicated by their strong interrelationships (Table 2). For example, Quetelet index and the waist, hip, and bust girths all showed correlations ≥0.80 with each other. In contrast, Quetelet index was only moderately associated with WHR (r = 0.28), and with wrist and ankle circumferences (r < 0.40). Except for WHR, age was only weakly related to the anthropometric variables. (Spearman correlations yielded very similar results; for example, the rank-order correlation between waist and hip girth was 0.82.)

Because all girth measurements increased with the degree of overweight, partial correlations were used to examine interrelationships among the girth measures independently of Quetelet index. Results in Table 2 (in parentheses) show that adjusting for overweight markedly reduced the intercorrelations among the girth measures. For example, correlations with hip girth decreased from r = 0.83 to 0.36 (for waist) and from r = 0.55 to 0.10 (for neck). Furthermore, wrist and ankle circumferences

TABLE 2—Interrelationships[a] among the Anthropometric Variables

	Quetelet Index	Age	Waist	Hip	WHR	Bust	Neck	Wrist
Quetelet index								
Age	.03							
Waist	.84	.14 (.22)[b]						
Hip	.88	.01 (−.03)	.83 (.36)					
WHR	.28	.25 (.25)	.62 (.74)	.09 (−.36)				
Bust	.81	.01 (−.03)	.85 (.53)	.80 (.31)	.40 (.30)			
Neck	.58	.09 (.08)	.62 (.30)	.55 (.10)	.34 (.22)	.59 (.25)

Ankle	.38	.06 (.05)	.35 (.05)	.39 (.11)	.09 (−.03)	.32 (0)	.36 (.19)	.45 (.36)

[a]Pearson correlation coefficients.
[b]Partial correlation coefficient, adjusted for Quetelet index and (Quetelet index)^2, is shown in parentheses.

were only weakly associated with the truncal (bust, waist, and hip) girths after controlling for Quetelet index. Additional adjustment for age did not alter these correlations.

The prevalence of diabetes was then examined after cross-classifying Quetelet index with each girth measurement (Table 3). As assessed by a test for trend (while controlling Quetelet index), diabetes was strongly related to WHR and waist, neck, and bust circumferences, with adjusted ORs ranging from 2.2 to 4.0 for women in the upper tertile of these girth measurements. Similar results were seen within each quintile of overweight: for example, the prevalence of diabetes increased from 1.9 to 6.0 per cent with increasing waist girths in the lowest Quetelet index quintile, and comparable increases were seen within other strata of Quetelet index. (Very little residual confounding was present in these analyses: as waist girth increased among women in the lowest overweight quintile, mean levels of Quetelet index were 23.4, 23.9, and 22.7 kg/m^2.) Although associations with WHR and both neck and bust girths were also similar across quintiles of overweight, diabetes was most strongly related to wrist and ankle girths among very overweight (quintiles 4 and 5) women. Among women with a Quetelet index >34.6 kg/m^2, the prevalence of diabetes *decreased* from 10.9 to 9.2 per cent with increasing ankle girth, and from 11.1 to 9.1 per cent with increasing hip girth.

Logistic regression was then used to determine which circumference measurements remained related to diabetes mellitus after controlling for all variables, and the final estimates of a stepwise procedure are shown in Table 4. Because dummy variables, representing tertiles of the pre-

TABLE 4—Logistic Regression Analysis of Diabetes Mellitus and Girth Measurements

Predictor Variable[a]	Odds Ratio for Diabetes Relative to Women in Lowest Tertile[b]		Increase in −2 × Log likelihood[c]	P-Value
	Middle	High		
Waist	1.5	2.6	802	<0.0001
Age	1.8	2.8	270	<0.0001
Neck	1.1	1.7	99	<0.0001
Bust	1.1	1.6	35	<0.0001
Hip	0.69	0.61	21	<0.0001
Ankle	0.83	0.73	11	0.003
Quetelet index	1.2	1.4	12	0.002
Wrist	1.0	1.3	10	0.006

[a]Independent variables are listed in order of entry in a stepwise procedure.
[b]Each predictor variable was categorized into tertiles; cutpoints are shown in Table 3. Odds ratios are estimated from the final model which includes all predictor variables.
[c]−Log likelihood of model containing only the intercept is −8062 versus −7432 for full model. 2 × increase in −log likelihood for each predictor variable is approximately distributed as a chi-square statistic with 2 df.

dictor variables were used in these analyses, the estimated ORs indicate the odds of diabetes for women in the upper (or middle) tertile vs the odds of diabetes for women in the lowest tertile. Models that used interval scales for these variables yielded similar results (data not shown).

All circumference measurements provided additional information concerning diabetes. Although older (>47 years of age, upper tertile) women showed the largest OR (2.8) for diabetes, large waist girths were independently associated with an OR of 2.6. Large neck and bust girths further increased the risk of diabetes by 60 to 70 per cent, and a high Quetelet index by 40 per cent. However, at similar levels of the other variables, women with relatively large hip and ankle girths were *less* likely to be diabetic (ORs of 0.61 and 0.73, respectively). Additional models that included WHR (rather than waist and hip girths as two separate variables) yielded an OR of 1.9 for WHR; however, coefficients for the other variables were virtually identical to the estimates in Table 5.

The improved prediction of diabetes by the use of bust, neck, and wrist girths is shown in Figure 1 for the 35- to 46-year-olds (middle tertile of age). An OR of 3.9 was obtained if the prevalence of diabetes was contrasted between women in the upper and lower tertiles of Quetelet index, and this association increased to 7.3 if high levels of Quetelet index and WHR were contrasted with low levels of both variables. By using the bust, neck and wrist girths, the OR reached 9.7. However, in conjunction with these higher ORs (and positive predictive values), the sensitivity was reduced. Quetelet index alone had a sensitivity of 62 per cent (420/680) in identifying diabetic women, whereas the sensitivity of all five anthropometric variables was only 6 per cent (41/680).

Discussion

The importance of body fat distribution as an independent risk factor for diabetes mellitus has only recently been appreciated.[29,30] Although various skinfold and circumference measurements have been related to metabolic complications,[8–11,13–15] the current findings indicate that waist and hip girths do not completely summarize all of the detrimental aspects of adipose tissue distribution. After controlling for age and Quetelet index in the current study, diabetes mellitus was positively related to waist girth, and was inversely related to hip girth. However, even after accounting for these characteristics (or alternatively, for age, Quetelet index and WHR), diabetic women had larger neck, bust and wrist girths along with *smaller* ankle girths than did nondiabetics.

These findings indicate that diabetic women have a relative preponderance of adipose tissue in various regions of the upper (vs lower) body. Consistent with these results, Vague, *et al*, have argued that android obesity is not limited to one particular area, and correlations between android obesity and WHR are only moderate.[5,20] Furthermore, in

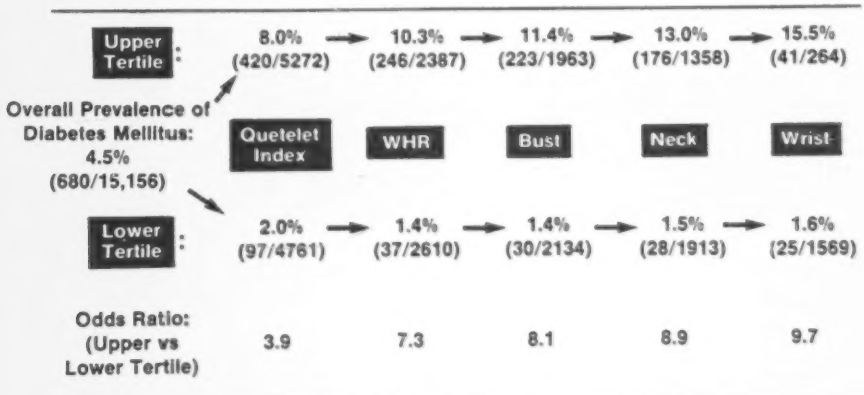

FIGURE 1—Improvement in the Prediction of Diabetes Mellitus among 35- to 45-year-old Women by the Use of Various Anthropometric Measurements

NOTE: The prevalence of diabetes for women in the upper vs lower tertile of each variable is contrasted. For WHR (waist to hip ratio) and subsequent variables, contrasts are restricted to women who were in the extreme tertiles for all previous measurements.

addition to WHR, other patterns of body fat distribution are deleterious: diabetics have relatively lean calf skinfolds[6,9] and an excess of subcutaneous fat in the subscapular region.[6,8,10] Because there are numerous patterns of fat topography that resist simple classification,[19] the current results suggest that a simple ratio cannot summarize all of the aspects of body fat distribution that increase the risk of diabetes mellitus.

Although girth measurements, particularly on the trunk, are related to the level of overweight, the importance of WHR (as an index of body fat distribution) has been demonstrated in studies that controlled for per cent body fat as determined from hydrostatic weighing.[31] Furthermore, after controlling for Quetelet index in the current study, both hip and ankle girths were *inversely* related to the prevalence of diabetes. Therefore, it is unlikely that circumference measurements merely provide a better indication of the total amount of adipose tissue. These findings, as do those of Mueller, *et al*,[16] indicate that combinations of circumference measurements are useful in describing body fat distribution. However, as compared with skinfold thicknesses, girth measurements are more reliable and can be assessed even in very obese persons.[32]

Although circumferences include other body components in addition to adipose tissue, individual truncal girths are strongly related to body fat. For example, Steinkamp, *et al*,[33] found that in middle-aged White women, body fat (as calculated from tritium dilution) was as strongly related to waist and chest girths as it was to the scapular skinfold thickness (r = 0.86 to 0.88). Furthermore, possibly because they include internal (as well as subcutaneous) adipose tissue, combinations of truncal circumferences are better predictors of total body fat than is ultrasound.[34] The observed relation of neck circumference to diabetes is in agreement with Vague's finding[5] of an increased skinfold thickness at the nape of the neck in women with android obesity.

In contrast, wrist and ankle girths are only weakly correlated (r = 0.1 to 0.6) with total body fat in women,[33,35] and are good measures of frame size in lean adults.[36] In these data, associations between diabetes and these circumferences were most evident among very overweight women (Table 3), suggesting that these peripheral girths may partly reflect regional fat deposition. The inverse relation of ankle circumference to diabetes is consistent with the contrast of upper- and lower-body obesity, and with the observation that diabetic women have relatively lean calves.[6,9] (Although ankle girths may be subject to greater misclassification than are other circumferences, nondifferential errors in measurement cannot explain its inverse association with diabetes mellitus.) However, it is possible that frame size, as assessed by wrist and ankle girths, is an additional risk factor: persons who are overweight without being obese may be at increased risk for hypertension and hypercholesterolemia.[37]

The association between both body fat patterning and clinical complications may be medicated by a third factor (sex hormones[15]), but there are several mechanisms whereby certain deposits of adipose tissue could result in metabolic disturbances. Decreases in both skeletal muscle sensitivity to insulin[38] and hepatic removal of insulin[15] are found in women with a high WHR, even after accounting for the degree of overweight. Furthermore, as compared with the femoral-gluteal region, abdominal fat cells show high rates of lipolysis.[39] Because free fatty acids from intra-abdominal adipocytes can drain directly into the portal circulation, the amount of intra-abdominal fat, which is highly correlated with WHR, may be the most important aspect of fat topography.[15]

Similar mechanisms may also be involved in other localizations of body fat; for example, mammary adipocytes also show high rates of lipolysis.[40] In agreement with the current findings concerning the importance of breast circumference in differentiating between diabetic and nondiabetics, previous studies have shown that: 1) the contrast of subscapular (rather than waist) and lateral calf skinfolds is optimal,[9] and 2) the subscapular skinfold thickness region is preferable to that in the abdominal region.[6] Furthermore, the subscapular skinfold is a slightly better predictor of coronary heart disease than is the abdominal skinfold.[41]

Although limitations of the cross-sectional study design should be considered, several of the possible biases would have reduced the magnitudes of the observed associations. Information was obtained by self-reports and it is likely that there was substantial misclassification of both diabetes and girth measurements. However, because women in TOPS were health-conscious, misclassification of diabetes was likely lower than that in the general population. Furthermore, any nondifferential misclassification would have resulted in an underestimation of the importance of girth measurements. Although it is also possible that overweight diabetics may have been more likely to join TOPS than were either overweight or diabetic women, this selection bias cannot explain the negative associations with hip and ankle girths, and because diabetic women may be motivated to lose weight, the observed associations may have underestimated the importance of body fat distribution. Additional analyses restricted to diabetics who were diagnosed within the last year (n = 461), however, yielded results that were similar to those observed among all diabetics.

Although few cohort studies have included baseline information on circumferences, the importance of WHR in the subsequent development of diabetes mellitus has been confirmed.[14] The current findings, however, indicate that an adverse localization of adipose tissue fat is not limited to the abdominal region, and that a generalized pattern of upper-body obesity is associated with diabetes mellitus in women. In addition to waist and hip circumferences, other girth measurements are needed to adequately characterize all of the detrimental aspects of body fat distribution.

Optometry Journal Has New Name

The name of the journal of the American Academy of Optometry has been changed—from *American Journal of Optometry and Physiological Optics* to *Optometry and Vision Science*. Along with the shorter name, the journal changed its size and format as well. Now printed in the "A" size (8½ by 11 inches), the periodical bears the official color of the Academy—sea-foam green—and announced additional changes, including: larger, easier-to-read print, a new section dealing with statistics, more use of color, and more invited editorials.

Optometry and Vision Science is currently edited by William M. Lyle, OD, PhD, School of Optometry, University of Waterloo, Canada, and is published by Williams and Wilkins, 428 East Preston Street, Baltimore, MD 21202. Contact the publisher for a sample copy of the journal.

The Acceptance and Completion of Mammography by Older Black Women

ROBERT C. BURACK, MD, MPH, AND JERSEY LIANG, PHD

Abstract: We assessed the relation of patient characteristics, knowledge and beliefs to the utilization of mammography in an inner-city setting by 187 Black women over the age of 50. Thirty per cent of those who were offered mammography initially declined the offer and 40 per cent were subsequently unable to complete the procedure. Patient interviews were used to derive 27 potential knowledge and health belief predictor scales. In multiple regression analysis, two health belief scales and two knowledge scales accounted for 15 per cent of the observed variance in the model of acceptance. The strongest predictor of subsequent completion was initial acceptance. The presence of breast symptoms and two health belief scales together with initial acceptance accounted for 26 per cent of variance in the model of completion. These results suggest that the successful accomplishment of mammography requires coordinated efforts at the level of the provider, patient, and setting. Health beliefs may influence the patient's behavior in this process, but their effect appears to be modest. (*Am J Public Health* 1989; 79: 721–726.)

Introduction

Breast cancer is the leading cause of cancer mortality among Black women in the United States.[1,2] Programs of early detection can lower this risk by up to 40 per cent,[3,4] and thus standard medical practice protocols recommend periodic mammography for all women over the age of 50.[5,6] Nonetheless, only about 15 to 20 per cent of women over age 50 in the general population report ever having had a mammogram,[7–9] even though over 75 per cent of US women visit a physician each year.[10] No more than 4 per cent to 40 per cent of those studied in various medical settings receive mammography.[11–17] The accomplishment of mammography within these settings requires that physicians offer the procedure to patients who accept the recommendation within a framework which facilitates completion. Potential barriers include physician behavior (offering), patient behavior (acceptance), and logistic factors (such as cost, transportation, time).

We have previously noted that in a primary care setting serving an inner-city Black population, 20 per cent of female patients who were offered mammography initially declined the offer and nearly 40 per cent failed to complete the procedure.[18] Observations in our own and other settings have led to inconsistent conclusions concerning the relevance of patient health beliefs to participation in programs of early cancer detection.[18–23] We therefore conducted a prospective assessment of the relation of patient demographic characteristics, health status indicators, cancer control knowledge, and health beliefs to acceptance and subsequent completion of mammography among a group of older Black women in a primary care setting.

Methods

Subjects were recruited from patients visiting an Internal Medicine teaching practice during the period August through November 1985. The practice serves a population which is predominately Black, elderly, and of lower socioeconomic status. The practice was staffed by 16 resident physicians, one clinical nurse specialist, and three faculty internists, all of whom participated in the study.

At the conclusion of each patient visit during the study period the primary provider completed an encounter form which documented the provider's recommendation (offering) of any of three index procedures (Pap smear, mammography, home occult blood testing) to female patients over the age of 50. Following their visit, potential subjects were telephoned at home by a research assistant, informed consent for participation was requested, and those agreeing were then interviewed using the instrument described below. Of 474 potential subjects, 97 (20 per cent) declined participation, five (1 per cent) terminated the interview prematurely, and 72 (15 per cent) were unavailable (primarily due to absent phone service). The 300 participants were demographically similar to those declining the interview (mean age 67.4 versus 66.6 years) but did appear somewhat more likely to initially accept the offer of mammography (69 versus 63 per cent). Among the 300 interviewees, 207 had been offered mammography, and 276 were Black. The 187 Black interviewees offered mammography constitute the subjects of this report.

In our setting, mammography is provided via individually scheduled appointments. Following each visit during which mammography was recommended, the primary provider indicated the category of the patient's initial response as follows: *acceptance* (mammography appointment scheduled); *deferral* (patient request to delay consideration); *refusal* (patient rejection of the recommendation). Subsequent analyses contrasted those initially accepting the recommendation with those initially declining (defer plus refuse). Completion of mammography was documented through a review of the medical record and a computerized billing search conducted six months following the date of offering to allow an adequate interval for procedure completion.

The interview instrument employed was based upon the conceptual framework of the Health Belief Model[19] and included the dimensions of: knowledge, perceived severity, perceived susceptibility, perceived utility, perceived barriers, behavioral intentions, and cues to action. Items were derived from previous work by the authors and from review of previously published instruments, with particular emphasis on those assessing older and Black individuals.[18,20–28] The resulting final instrument contained 127 items and required no more than 45 minutes to complete.

Principal factor analysis with varimax rotation (SPSSx) was used to derive factors within each conceptual dimension (knowledge, susceptibility, etc). Internal consistency was determined using Cronbach's coefficient alpha which ranged

from 0.45 to 0.97 with 24 of 27 factor alphas exceeding 0.60. Scales were then constructed by summing equally weighted item responses for each factor (see Appendix).

We measured the bivariate unadjusted relations of the demographic characteristics, health status indicators, interview scales, to mammography utilization via Pearson correlation and stratified analyses contrasting the effect of scale values classified as high, moderate, or low (generally employing cutpoints at the 75th and 25th percentiles, depending upon the frequency distributions). In preliminary regression analyses, we fitted models for each individual block of variables (demographics, health status indicators, knowledge and health belief domains) with acceptance or completion as the dependent variable. We then developed separate individual models of acceptance and completion, employing only those predictor variables which seemed reasonable and were independently significant at the 0.10 level in the initial analyses (Table 2). Results from linear models are presented here; logistic analyses gave similar results. Estimates of marginal and composite probability were derived from the logistic models.[29] The SPSSx and BMDP software packages were used for all statistical analyses and two-tailed tests of significance are reported.

Results

The average age of the 187 interviewees was 67.1 years (S.D. = 10.6). Seventeen per cent were currently married and half lived alone. Nearly 70 per cent reported household incomes less than $5000, 11 per cent were currently employed, the mean education level was 9.0 years (S.D. = 3.1), and all had some form of third party payment. The prevalence of chronic illness was high: over three-fourths had hypertension, nearly one-half manifest heart disease, one-third had diabetes mellitus, and 40 per cent had osteoarthritis. All were ambulatory and residing in the community.

Of the 187 subjects offered mammography, 131 (70 per cent) initially accepted, 42 (22 per cent) deferred, and 14 (7 per cent) refused the offer. Overall, 109 (60 per cent) of patients offered mammography were able to complete the procedure during the six-month period of follow-up. Completion was more likely among those initially accepting the offer, but some who initially accepted did not complete mammography and vice versa. Overall, 75 per cent of those initially accepting the offer completed mammography, as contrasted with 29 per cent of those initially deferring, and 8 per cent of those initially refusing.

Results from the patient interviews are presented in the Appendix. Overall, knowledge of cancer control was limited although 90 per cent believed that early detection in general was useful. Only one-third identified breast cancer as curable if detected early. Thirty per cent mentioned mammography as a potentially useful early detection procedure and half could accurately define mammography.

Most women perceived the lifetime risk of breast cancer in the population as two to four times the actual risk (median response 25–50 per cent), yet only 5 per cent viewed cancer as very likely in their own lifetime and only 1 per cent specifically identified cancer of the breast as a future health concern. Still, nearly 50 per cent acknowledged that they worried about getting cancer or that tests might detect cancer. Furthermore, 60 per cent felt they had no control over getting cancer and that there was "no point in worrying about cancer now" since it was unavoidable.

Perceived barriers to early detection included the expense of an office visit (40 per cent) or of mammography (23 per cent). Mammography safety, discomfort, or fear were each cited by less than 13 per cent as having any importance as potential barriers.

The interrelations among the potential predictor variables were relatively weak for the most part, thus limiting the potential effect of multicollinearity. Age, education, and knowledge scores did demonstrate relationships with selected health beliefs in the expected direction. Overall, of the 406 interscale bivariate correlation coefficients only 31 exceeded 0.3 and, of these, three exceeded 0.6, i.e., *utility of tests* (likelihood of behavior change); *emotional arousal* (level of concern); *futility of cancer treatment* (knowledge of prognosis).

The unadjusted relation of selected demographic and interview scale variables to the acceptance and completion of offered mammography is presented in Table 1. Older, asymptomatic women with more frequent medical conditions were less likely to accept and complete mammography. Acceptance and completion were also associated with: knowledge of the procedure; belief that testing, early detection, and treatment were useful; and belief that cancer was avoidable. Women who discounted the importance of expense, fear of detection, embarrassment, and procedure discomfort as barriers were more likely to accept and complete mammography.

The results of the multiple regression analyses are presented in Table 2. The previously described bivariate intercorrelations noted between predictor variables and the relatively skewed distribution of some of the belief scores (Table 1, particularly barriers 2–5) accounted for the exclusion of the variables in Table 1 that were not in the final multivariate models. We observed no independent relation between any of the demographic or health status indicators with initial acceptance of mammography. Women who knew more about the detection procedures and recognized the increased risk of cancer with age were more likely to accept, other factors being equal. Health beliefs independently associated with acceptance included the belief that early treatment of cancer was useful, and a discounting of the importance of procedure expense as a potential barrier to mammography accomplishment. Overall, these four scales accounted for 14.5 per cent of the observed variance in mammography acceptance (95% CI = 7.7, 34.4).

Initial acceptance strongly predicted mammography completion, as expected. One health status indicator and two health belief scales also contributed independently to the final model. The presence of breast symptoms, discounting of expense as a barrier, and higher assigned utility of cancer detection tests, together with initial acceptance, accounted for 26 per cent of the observed variance in the final model of mammography completion (95% CI = 18.8, 55.3).

As shown in Table 3, the magnitude of the independent effects (marginal probabilities) of each of the four predictor variables in the acceptance model varied between 5 per cent and 9 per cent. For example, a one-point increase in the health beliefs scale for utility of treatment was linked to an increase of 8 percentage points (95% CI = 2.9, 13.1) in acceptance. The presence of symptoms was linked to an increase in completion of 15.5 percentage points (90% CI = .6, 30.4). Table 3 presents estimates of the probability of acceptance and completion, based upon the logistic models, for various combinations of predictor variables. The estimated probability of mammography acceptance among those with higher belief scores rose from 66 per cent among those with low scores on the knowledge scales to 92 per cent for

*Significant at the 0.10 level in bivariate analyses.

those with high scores. Table 3 also includes the observed rates of acceptance and completion for comparison with the model estimates. It should be noted that the small number of individuals manifesting concurrently low values on each of the relevant health belief scales precludes calculation of rates for those groups.

Discussion

Successful cancer control in the primary care setting requires that detection procedures be offered by physicians to patients who then accept and are able to complete the procedure. We have observed that even among women offered the procedure, personal and logistic factors are important determinants of subsequent acceptance and completion of mammography. While provision of mammographic services to a substantial number of the patients we studied is encouraging, those remaining at risk for nonparticipation constitute an important focus for study.

The role of health beliefs in this process is complex. Our data suggest that patient beliefs only weakly influence initial acceptance and subsequent procedure completion. After controlling for the interdependence of the multiple potential predictors, only two knowledge variables (detection procedures, age risk) and two belief scales (utility of early treatment, importance of expense as a barrier) remained as independent predictors of mammography acceptance and together accounted for 15 per cent of the observed variance. After controlling for initial acceptance, subsequent completion appeared more likely among women who presented with a sign or symptom of breast disease, who believed in the utility of early detection tests and who discounted expense as a barrier. The inverse relation noted for external prompts may suggest that intrapersonal factors are the more relevant but this must be interpreted with caution. While this model explained 26 per cent of the variance in completion, initial acceptance accounted for the largest component. Previous studies of patient participation in early detection programs for breast as well as colon cancer have also reported only modest effects for health beliefs.[22,23] These observations lead us to conclude that factors other than patient beliefs must be considered if mammography utilization is to improve our setting.

Mammography appears substantially underutilized as a cancer control tool in most reported settings.[11–17] Our findings emphasize that the process of mammography utilization begins with a physician decision to recommend the procedure but then depends upon the successful interaction of patient, physician, and setting. McCusker and Celantano have suggested that physicians may operate as potent reinforcers of patient decisions regarding early cancer detection, perhaps consistent with our observation of subsequent examination completion among women initially deferring or refusing the procedure.[21,30] We have not, however, assessed the interactional dynamics of the offers, nor those factors associated with the physician's decision to recommend mammography to an individual patient.

This study and previous observations have also emphasized the importance of logistic factors such as procedure cost as potential barriers.[31] Although all of our subjects had health care insurance, coverage for preventive services is variable and we do not have information on individual out-of-pocket expense. Nor have we directly ascertained the extent to which other logistic factors inhibited patient intention to complete mammography. Retrospective interviews may be useful to assess experienced barriers and would complement prospective ascertainment of predictive characteristics.

Our focus has been the relevance of potential barriers to the utilization of mammography among older, Black women and thus our conclusions may not apply to other settings. Education, knowledge of cancer control, and resources were limited among our subjects. National surveys, however, have also demonstrated a surprising degree of misinformation regarding cancer among many groups, including but not limited to older and minority subgroups.[24,28]

*Overall probability of acceptance = .71
**Overall probability of completion among asymptomatic women = .58
***Scales in acceptance model include utility of treatment and discounting expense barrier. Scales in completion include utility of tests and discounting expense barrier.

Several other limitations of this study must be acknowledged. Nearly one-third of all potential subjects were not interviewed. While the initial mammography acceptance rate among those not interviewed was similar to that observed among the participants, we have no information concerning their subsequent behavior or their beliefs. Furthermore, the response rate specifically among Black women could not be measured. Second, health beliefs are complex constructs and no reference standard for their assessment is available. In addition, incorporation in our models of unmeasured but relevant variables or study of a sample manifesting broader variability could alter our estimates. Finally, even if these results are correct for this population, we do not know how generalizable they are.

Successful cancer control in the primary care setting will likely require complementary interventions at the level of patient, provider, and institution. Structural interventions which limit cost or which otherwise facilitate completion are fundamental. Certainly, patient beliefs are not irrelevant to this process. Furthermore, while their influence may be limited, health beliefs are potentially modifiable and thus of clinical relevance particularly in a population characterized by limited knowledge of cancer control activities. However, our work and that of others reinforces the need to interpret patient beliefs in the broader context within which decisions are made and action carried out. This broader view of physician and patient behavior holds the most likely promise for cancer control in the primary care setting.

ACKNOWLEDGMENTS

We are indebted to the subjects and physicians who participated in this study, and to Joan Bennett, Renee Lawrence, and Barbara Moore for technical assistance. This study was supported by a grant from the AARP Andrus Foundation. This study was presented in part at the 10th annual meeting of the Society for Research and Education in Primary Care Internal Medicine, San Diego, California, April 1987.

CDC's ACIP Updates General Recommendations on Immunization

The Immunization Practices Advisory Committee (ACIP), of the Centers for Disease Control, has updated its general recommendations on immunization. The revised version, which updates the 1983 statement, was printed in the April 7, 1989 issue of *Morbidity and Mortality Weekly Report* (MMWR) published by CDC. Changes or new sections in the revised recommendations include:

1) Listing of vaccines available in the United States by type and recommended routes of administration;
2) Updated schedules for immunizing infants and children;
3) Clarification of the guidelines for spacing administration of immune globulin preparations and different vaccines;
4) An updated table of recommendations for routing immunization of children infected with human immunodeficiency virus;
5) Listing of conditions that are often inappropriately considered contraindications to immunization; and
6) Addition of information on the National Childhood Vaccine Injury Act of 1986 and the National Vaccine Injury Compensation Program.

The *Morbidity and Mortality Weekly Report* is prepared by the Centers for Disease Control, Atlanta, Georgia, and available on a paid subscription basis from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, (202) 783-3238.

Psychiatric Disorders and 15-Month Mortality in a Community Sample of Older Adults

MARTHA LIVINGSTON BRUCE, PHD, MPH, AND PHILIP J. LEAF, PHD

Abstract: The relation between psychiatric disorders, defined by the Diagnostic Interview Schedule (DIS), and mortality over 15 months is compared in 3007 adults age 55 and over in the New Haven Epidemiologic Catchment Area (ECA) project. Our results indicate that the odds of dying are more than four times greater for individuals with affective disorders than for others in the sample, controlling for age, sex, and physical health. Cause of death is also examined. There were no suicides or deaths from external causes. (*Am J Public Health* 1989; 79:727–730.)

Introduction

In the past decade, a number of studies have examined the prevalence of psychiatric disorders in the community.[1,2] While these disorders exact their toll on the quality of individual lives, follow-up studies of patients in treatment suggest that certain psychiatric disorders also increase the risk for death.[3–5] However, only a few studies have examined the effects of specific psychiatric disorders on mortality in community samples and these yield inconsistent results.[6,7]

The Epidemiologic Catchment Area (ECA) project was designed to assess the prevalence of major psychiatric disorders in community samples. In its follow-up, the study collected mortality data, providing a unique opportunity to examine the relationship between overall and cause-specific mortality and psychiatric disorders in the older members of the sample while controlling for a number of known predictors with mortality.

Methods

Data for these analyses were collected as part of three waves of the New Haven portion of the ECA project, a collaborative multi-wave study of the incidence and prevalence of major psychiatric disorders and the use of health and mental health services. Beginning in July 1980, interviews were obtained from a multistage probability sample of 3,058 adults age 18 years and over living in a 13-town region comprising the greater New Haven community (total adult population of approximately 300,000). An additional sample of 1,976 elderly respondents age 65 and over was also assessed. The sampling frame stratified data collection among the 13 towns; household and elderly oversample respondents were selected from among clusters of eight households at intervals of 60 households within each of the 13 strata. Only one respondent was interviewed from a household. The methods used in ECA project are described in greater detail elsewhere.[8–10] The total of 5,034 interviews represents an overall response rate for the first wave of the survey of 77 per cent. Because the observed 15-month mortality is so low in the younger (ages 18–54) age group (three deceased or 0.1 per cent), we examine mortality only among the 3,007 respondents age 55 and over.

Two follow-up contacts were scheduled in an average follow-up period of 15 months. In this analysis, wave 1 respondents identified by informants as having died over the course of the follow-up period are compared to the remaining wave 1 sample. This approach assumes that respondents lost to follow-up survived the 15-month period. However, because the current study is preliminary to a planned long-term follow-up of the full wave 1 sample, we have not been able to confirm this assumption. The group lost to follow-up includes: 48 respondents not found at the second wave; 497 respondents who were alive at the second wave but refused to be reinterviewed and were therefore not contacted at the third wave; and 14 respondents who were interviewed at the second wave but could not be located at the third wave. These 559 respondents did not differ from the rest of the sample by age, sex, or lifetime or recent psychiatric disorders although they were more likely to be in good physical health or to be cognitively impaired. Including them in these analyses as living respondents results in a more conservative estimates of the effects of psychiatric status on mortality than omitting them from the analysis. With this group omitted, the only difference in results was an increased effect of recent schizophrenia on mortality in the comorbidity model.

During this period, 136 (4.5 per cent) of our sample of adults age 55 and older were identified by informants as having died. This is 25 fewer deaths than the number expected based on national age-sex-race specific mortality rates in 1980, suggesting that there may have been some deaths among the respondents lost to follow-up. Using local and state resources, 131 of the 136 (97 per cent) of the deaths have been verified by death certificates. Cause of death was extracted from the death certificates and classified with the assistance of a physician. Of the unconfirmed deaths, one reportedly occurred outside of the United States and at least one occurred to respondents who moved from Connecticut during the study period.

Psychiatric status was assessed by the Diagnostic Interview Schedule (DIS), a structured interview designed for use by lay interviewers in epidemiologic studies and capable of generating diagnoses for the more prevalent psychiatric disorders.[11] The DIS ascertains information about both the existence and severity of symptoms, and computer algorithms determine whether these meet DSM-III* criteria for specific psychiatric disorders. Severe impairment in cognitive functioning at the time of the interview was assessed by the Mini-mental State Examination.[12] The likelihood of mortality is compared using logistic regression for individuals

meeting lifetime or recent (within six months of the interview) criteria for any of four groups of psychiatric disorder or for cognitive impairment. The disorder groups examined include affective disorders, anxiety disorders, substance abuse or dependence, and schizophrenic disorders.

Controls include age (in years), sex, and baseline physical health status. Physical health status was assessed by asking respondents whether they had a history of any of a variety of chronic health problems (hypertension, heart attack, stroke, cancer) or any limitation in physical functioning.[13] Approximately 80 per cent of the sample of adults age 55 and over reported physical health problems using these criteria. Although this represents a gross assessment of health, the crude relative risk of 15-month mortality for respondents age 55 and over associated with poor health is 6.38, a figure comparable or greater than observed with measures used in other studies of older adults.[14,15]

Results

As seen in the first column of Table 1, mortality rates varied considerably by psychiatric status. The percentage deceased was greatest among those with affective disorders (10.9 per cent for those meeting criteria within six months of the interview), schizophrenic disorders (14.3 per cent for recent and 6.3 per cent for lifetime), and severe cognitive impairment (9.0 per cent). Adults age 55 and over who had an affective disorder, schizophrenia, or cognitive impairment within six months of the initial interview had at least 150 per cent greater chance of dying in the following 15 months than did other members of the sample. The odds ratios also indicate the relatively low risk of mortality in this sample among those with anxiety disorders (0.9 for recent and lifetime) or who abuse drugs or alcohol (0.8 for recent and 1.1 for lifetime).

The far right column in Table 1 presents the odds ratio and 95% confidence interval of dying (adjusted for sex, age, and physical health status using logistic regression). These adjusted estimates indicate that the high mortality associated with affective disorders (2.97 for recent and 1.83 for lifetime) was independent of sex, age, and physical health status. The association with schizophrenia is also strong (3.94 for recent and 1.82 for lifetime disorders) but the small number of cases (N = 7) yielded an extremely wide confidence interval. In contrast, the risk of dying associated with cognitive impairment is reduced considerably, from 2.5 to 1.43, once sex, age, and physical health status are controlled.

The effects of comorbidity among psychiatric disorders were controlled using a logistic regression model with all recent psychiatric disorder groups and cognitive impairment entered with sex, age, and physical health status. As seen in Table 2, men were 2.83 times more likely to die than women over the course of the 15 months, the likelihood of dying increased with age, and those in poor physical health are 4.31 times more likely to die than those in good health. The odds ratios associated with each of the disorder groups were similar to the adjusted estimates reported in Table 1 except for the affective disorders which increased to 4.31 when controlling for comorbidity.

To test whether the effects of recent affective disorders on mortality were stronger when accompanied by physical health problems,[15] we added an interaction term to the logistic regression model reported in Table 2 even though there were few affective cases in each physical health status cell. The interaction was significant ($p < .01$), although not in the expected direction, as illustrated by the crude mortality rates disaggregated by affective and physical health status in Table 3. Affective disorders increased the odds of mortality for those both with and without physical health problems, but the effect was greater for those reporting no physical health problems.

When we stratified the recent affective cases by type of disorder, we found that all the deaths were among those individuals meeting criteria for major depressive disorder (without a history of manic episodes) and none were among those with bipolar disorder. Of recent major depressives, five (12.5 per cent) died during the study period. Among lifetime cases not reporting a recent episode, one of the 36 (2.8 per cent) with major depression and one of the three (33 per cent)

with bipolar disorder had died. Few adults over age 55 in our sample had a history of bipolar disorder but, in these data, the risk of mortality among those with affective disorders was strongest for those with major depression, especially recent episodes.

Finally, we obtained cause of death from death certificates and compared the causes of death between psychiatric cases and noncases. Among the deceased, 63 per cent had died from vascular-related (cardio and cerebral) problems, 22 per cent from cancer, and the remaining 15 per cent from other causes, primarily pulmonary diseases. We found no evidence that any of the respondents committed suicide or died from other unnatural causes. Overall, the distribution of causes of death did not differ between psychiatric cases and noncases. While there was some variation in the distributions of causes of death among the psychiatric disorder groups, the small number of cases in each precludes generalizing from these observations. Among the depressed respondents who died during the study period, two died from heart-related problems, two from cancer, and one from respiratory arrest due to septic shock.

Discussion

These data suggest that premature mortality is associated with some, but not all, psychiatric disorders for adults age 55 and over. In this study, the risk was greatest for individuals meeting criteria for an affective disorder, specifically major depressive disorder, within six months of their interview. Because these analyses controlled for physical health status, the increased odds of death for individuals with an affective disorder cannot be attributed solely to comorbidity with physical health problems. Moreover, although the number of individuals with an affective disorder who report no history of physical health problems was small, the risk of mortality was at least as great for this group as for affective cases reporting physical health problems.

TABLE 3—Percentage Deceased (unadjusted) by Physical Health Status and Affective Disorders

	Recent Affective Disorder			
Physical health problems	No	%	Yes	%
No	(4/581)	0.7	(1/4)	25.0
Yes	(126/2368)	5.3	(4/42)	9.5

NOTE: Interaction between physical health and affective disorders significant ($p < .01$) adjusting for sex and age.

This examination of the effects of DSM-III diagnoses on mortality in a recent community sample of both treated and untreated persons augments the findings derived from groups of psychiatric patients,[4,5] from community samples which assessed depressive symptoms rather than diagnoses,[16] or from community samples in earlier decades.[6] In a review by Tsuang and Simpson,[3] Standardized Mortality Ratios in several patient studies of affective disorders range from less than 1 to 2.5 and in the follow-up of the 1952 Stirling County sample are approximately 1.6;[6] the relatively larger Odds Ratios of 4.31 for affective disorders found in the ECA data contradict the notion that the risk associated with these disorders for mortality is decreasing with time.

These findings are disturbing given the major advances in the treatment of affective disorders over the past three decades. Some evidence indicates that treatment can reduce the risk of premature death in affective patients.[17] Yet when we examined the treatment history of the affective cases who died in the 15 months following their initial interview, none reported being treated for mental health problems by a mental health specialist or general medical practitioner in the six-month period prior to the first interview and only one reported such treatment by a medical practitioner after the interview. While low usage of mental health services is consistent with older age groups in general,[9,10] the high risk posed by affective disorders warrants increased attention of all medical practitioners and care-givers to identifying and treating mental and emotional problems in older adults.

While this study confirms the risk associated with affective disorders for mortality even in recent cohorts of older adults, the data tell us little about the process by which this risk is increased. For example, for some individuals not evidencing physical problems, the depressive symptoms may be prodromal to conditions which will manifest in future months. For others, the impairment associated with depression may result in poor hygiene and nutritional neglect, increasing a person's susceptibility to physical health problems or exacerbating existing health problems. A longer period of follow-up will be useful in determining whether the high risk observed in this relatively short period persists over time.

In contrast, the apparent effect of cognitive impairment on mortality was largely explained by other factors. Because this result contradicts other studies, we examined whether the lack of effect reflected comorbidity between severe cognitive impairment and major depression. There were only three cases of comorbidity between the two disorders; none of these cases died during the study period. Indeed, when we examined comorbidity between mild cognitive impairment and major depression, none of these additional seven individuals died during the study period. The reduction in effects of cognitive impairment and mortality need to be attributed to the older ages and the increased problems in physical health and functioning of this group.

The apparent lack of effect of other psychiatric disorders, especially substance abuse on mortality, needs to be viewed in the context of the age of the sample and the relatively short follow-up period. Substance abuse problems generally begin in youth, therefore the negative effects of physical health and mortality may be more apparent in younger ages. The surviving substance abusers in the age 55 and over group may be qualitatively different from others. A longer follow-up of adults of all ages which takes into account

age of onset of substance abuse problems would help clarify this issue.

In conclusion, the 15-month follow-up of 3,007 members of the New Haven community, ages 55 and over, indicates that risk of dying is increased for those with major depressive disorder, even controlling for other known risk factors. In future research on this sample, we hope to examine the longer term effects of psychiatric disorders on mortality and learn more about the process by which psychiatric and physical health factors interact to affect mortal risk.

'Keep WIC Lit' Campaign to Help Hungry Women, Infants, and Children

Bread for the World, a Christian citizens' movement in the United States, has launched a campaign seeking full funding for the WIC program, one of the most effective government nutrition programs in the nation.

People are encouraged to mail a small birthday candle and a message—"Keep WIC Lit. Fully fund the WIC program so that more babies will celebrate their first birthday"—to their senators and representatives from now through August, to draw attention to the needs of millions of pregnant women, their infants and young children who are at nutritional risk.

The WIC program provides nutritious food, referrals to health services, counseling, and education to low-income women, new mothers, their infants and children up to age 5 years. The program saves US taxpayers millions of dollars a year; a Harvard study determined that every $1 spent on pregnant women in the WIC program saves $3 in hospital costs for newborns. The "Keep WIC Lit" campaign seeks increases of $150 million above inflation over each of the next five years in the WIC program so it can reach an additional 1.5 million nutritionally needy individuals. Less than half of those who are eligible are receiving WIC benefits at the present time.

Health Practices of the Elderly Poor

James E. Lubben, MPH, DSW, Philip G. Weiler, MD, MPH, and Iris Chi, DSW

Abstract: The purpose of the present study was to describe the health practices of the elderly poor and to examine the association between specific health practices and subsequent hospital use. Data came from a sample of 931 Medicaid elderly living in California. Smoking, limited social networks, and lack of regular exercise significantly increased the odds of subsequent hospital utilization. Implications of these findings, which could benefit health promotion intervention and treatment programs for the elderly, were discussed. (*Am J Public Health* 1989; 79:731–734.)

Introduction

There has been increasing attention paid to health promotion and disease prevention activities in the elderly because of economic, medical, and social concerns.[1,2] With increasing life expectancy, a focus on preventive measures to decrease morbidity and improve quality of life in old age has also developed.[3,4] To that end, health behavior and lifestyle have become important areas of concern over the last 20 years.

In the early 1970s, Belloc and Breslow[5] identified a list of seven health practices which were associated with health status: having never smoked; drinking less than five drinks at one sitting; exercising; sleeping seven to eight hours a night; maintaining desirable weight for height; avoiding snacks; and eating breakfast regularly. Inquiry regarding compliance with these practices has been included in the National Health Interview Surveys (NHIS) of the adult US population in 1977, 1983, and 1985.[6,7] Additional investigations have substantiated the importance of the smoking, drinking, exercise, and weight control health practices.[8–10] However, other practices have seldom been found to be significant.

More recently, other general health practices have also been suggested as important: maintaining a balanced diet (fruits, vegetables, and whole grains but limits on caffeine and salt intake) has been suggested as an important health practice,[1,11–13] and maintaining social networks.[9,14–20]

Current knowledge of specific health practices for elderly persons tends to be based on studies of younger populations. One of the few studies of an aged population reported that elderly who followed good health practices were not significantly advantaged in terms of mortality rates over a five-year period.[21] However, another study affirmed the value of some health practices for an elderly population when they examined mortality rates over a 17-year period,[10] finding that not smoking, getting regular exercise, maintaining weight control, and regularly eating breakfast were associated with lower mortality rates.

One aim of the present study was to evaluate the relative importance of specific health practices among elderly persons; another purpose was to explore differences in health practices of the elderly poor and the general elderly population.

Methods

Design

The data were drawn from the California Senior Survey (CSS), a random sample of elderly Medi-Cal (Medicaid) recipients from eight representative communities within California. Eligibility for Medi-Cal includes those elderly on Supplemental Security Income (SSI) or with incomes of $550.00/month (single aged) or less after accounting for medical expenses. The CSS respondents were randomly selected from files which contain the names, addresses, and other basic demographic data for all Medi-Cal recipients. Only Medi-Cal recipients 65 years of age and older were sampled. CSS respondents were interviewed face-to-face in 1982 and paid $15.00 for their participation. Hospital utilization data were also obtained for one year following the interview. Comparisons between the survey data and statewide data indicated that respondents were typical of California's Medi-Cal elderly population. More complete descriptions of the sampling methodology and sample characteristics have already been published.[22–24]

For the present analyses, data from the interview were merged with those from other sources regarding a respondent's hospital use during the year following the interview. The hospital utilization data came from Medi-Cal paid claims computer tapes which were merged with data obtained from Medicare intermediaries.[25] Combining these two sources provided complete data on number of days hospitalized for 90 per cent of the original CSS sample. To assure accuracy, the computer tapes were examined for any bills submitted for hospitalizations during the follow-up year to either Medi-Cal or Medicare intermediaries on behalf of CSS respondents. To overcome any problems that might have been caused by late billing, bills submitted up to two years following the interview were reviewed. No significant differences in characteristics were noted between survey respondents with and without complete hospital data. Only respondents with complete hospital data were used for the following analyses (N=931).

The study relied upon self-report data regarding health practices using a questionnaire composed of several previously described instruments.[22–24] Many of the questions on health practices were taken verbatim from the original Belloc and Breslow study.[5]

Participants

Reflecting the diversity of California's ethnic population, the sample included a sizable proportion of Blacks (17 per cent), Hispanics (13 per cent), and Asians (12 per cent) although a majority (58 per cent) were White. With respect to gender, there were approximately two females for every male. The average age was 77.2 years and a large majority (61 per cent) of the respondents lived alone. With respect to health, 36 per cent rated their health as good, 41 per cent rated

it fair, and 22 per cent rated it poor. More than 75 per cent of the CSS respondents had seen a doctor within the past three months.

Health Practice Variables

Appendix A describes the inquiry used to construct the health practice variables analyzed in the present study. Belloc and Breslow[5] definitions of health practice for smoking, sleep, limited snacks, and regular breakfasts were used. Because alcohol consumption was so limited among the elderly in the present sample (68 per cent abstained), differences in this commonly examined health practice could not be evaluated.

Hospital Use Variables

Two dichotomous variables measuring hospital utilization were used: whether a respondent had been hospitalized within a year following the interview, and whether a respondent experienced a hospital stay of six or more days in the year following the interview. The figure of six days was selected because it was slightly higher than the average length of stay for all respondents (mean length of stay = 5.2 days).

Analysis

The present analysis involved a series of logistic regression models examining the relation of the 12 health practices with the two indices of subsequent hospital utilization. Controlling for age and self-reported health status at the baseline interview enabled us to compare our results with those from an earlier study which used a similar analytic model.[10]

Results

Prevalence of Risk Factors

Table 1 reports the percentage of the sample who did not comply with a specific health practice. Typically, 20 per cent to 25 per cent of the sample did not comply with any given health practice. Considerably higher non-compliance rates were observed for weight control (36 per cent), never smoking (43 per cent), regular physical exercise (50 per cent), and seven to eight hours of sleep (60 per cent). Only 12 per cent of the sample drank five or more cups a day of coffee or tea.

Subsequent Hospitalizations

Table 1 also shows how non-compliance with a specific health practice affected the odds of subsequent hospital use. The practices with the largest odds ratios were the two smoking items. Elderly who had limited social networks were half again as likely to be hospitalized and have extended stays as were elderly with larger networks. Similarly, a minimal level of physical activity reduced the odds of any hospitalization as well as the chances for an extended stay. Although almost all of the remaining odds ratios were in the expected direction, the 95 per cent confidence interval included 1.00. Separate analysis was conducted on underweight and overweight risk factors but neither was related to hospital use. Thus, based upon the present study, the most important health practices for elderly persons appeared to be not smoking (ever or currently), maintaining social networks, and engaging in some form of physical activity at least once a week.

Since a major illness could have both changed an elderly person's health practices and also caused a hospitalization, the logistic regression models were modified to include a dummy variable indicating whether a respondent had been hospitalized in the year prior to the interview. The results of these additional analyses showed that maintaining social networks (OR 1.52; CI=1.08 2.12), not ever smoking (OR 1.59; CI=1.15, 2.21), and not currently smoking (OR 1.59; CI=1.08, 2.33) continued to be related to risk of any subsequent hospitalization. However, the importance of regular physical exercise was diminished (OR 1.29; CI=.95, 1.76). Similar results were observed when considering the risk of a stay of six days or more in a hospital: maintaining social

TABLE 1—Association between Behavioral Risk Factors and One Year All Cause Hospitalization Rates

networks (OR 1.57; CI=1.10, 2.26), not ever smoking (OR 1.76; CI=1.23, 2.53), and currently smoking (OR 1.70; CI=1.12, 2.58), were significant risk factors whereas regular physical exercise (OR 1.38; CI=.97, 1.95) was not.

Discussion

About 10 per cent of California's elderly are Medicaid beneficiaries, compared with a national average of 8.3 per cent. Thus California's elderly Medi-Cal recipients may be fairly similar to elderly Medicaid recipients in general. However, the Medicaid elderly respondents in the present study are only indicative of the poorest of the elderly poor. Many elderly with limited incomes are unable to qualify for Medicaid because of other assets such as a savings account in excess of $2000. Thus, only one-third of all US elderly persons below the poverty line receive Medicaid benefits.[26]

The present findings are subject to the limitations of all cross-sectional studies of health practices and so the reported relationships between health practices and hospitalization should be viewed as associational and not causal. However, the magnitude of the increased odds of hospitalization associated with smoking were similar to previously reported levels of association between smoking and mortality rates.[10,27] Further, the relation between social networks and hospital use in the present study was also similar to that reported between social networks and mortality rates.[9]

The present findings failed to support some health practices found significant in earlier studies. For example, weight control and regular breakfast were previously reported to be significantly related to mortality rates[10] but neither were related to hospital rates in the present study. Different dependent variables (hospital vs mortality) may have accounted for this difference in results. None of the dietary health practices were highly associated with hospital use but our measures were not very sensitive.

The prevalence of smoking, lack of exercise, and weight problems was particularly high among the California elderly Medicaid recipients. Since three-fourths of our sample had seen a doctor within the last six months, it would seem most appropriate that these health practices receive increased emphasis by physicians serving the elderly poor. However, increased physician attention to preventive medicine may require a re-examination of public and private health insurance coverage for the elderly. Somers argues this point very well by stating it makes no sense to reimburse a physician for treating an illness but not for preventive care that maintains health.[28] Because public funds are the primary source of support of health care for the elderly poor, public policy must address the issue of financing health promotion for this population.

ACKNOWLEDGMENTS

The data used in this analysis come from the California Senior Survey, which was the comparison group for the California Multipurpose Senior Services Project (MSSP), a US Health Care Finance Administration (HCFA 1115) research and demonstration project administered by the Health and Welfare Agency of the State of California (Grant #11-P-07553). APPENDIX A
Health Practices Variables used in the Analysis

Health Practice:	Questionnaire Item	Favorable Response
Smoking		
Ever	Have you ever smoked cigarettes regularly?	No
Current	Do you smoke cigarettes at the present time?	No
Social Networks	Series of questions covering following aspects of social networks: 1. Frequency of contact with a relative 2. Number of relatives seen monthly 3. Number of relatives feels close to 4. Frequency of contact with a friend 5. Number of friends seen monthly 6. Number of friends feels close to 7. Has someone to talk to about important decisions 8. Others talk to respondent when they have important decisions 9. Feels relied upon and helps others 10. Lives with others	Above lower quartile on the Lubben Social Network Scale[a]
Physical Activity	How often do you exercise, for example do calisthenics, vigorous gardening, or take long walks?	Weekly or more often[b]
Whole Grains	How many servings of bread, cereal, or whole grains do you eat in a day?	Two or more
Weight Control	What is your weight? How tall are you?	Between 10% underweight and 30% overweight[c]
Fruits and Vegetables	How many servings of fruits and vegetables do you eat in a day?	Two or more
Sleep Patterns	How many hours of sleep do you usually get at night?	Between 7 and 8 hours
Caffeine	On an average day, how many cups of coffee and tea do you drink?	Less than five[d]
Salt	How often do you eat salty type foods such as potato chips, pickles, lunch meats or canned soups?	Once in a while, rarely or never
	How often do you add salt to your food at the table?	Once in a while, rarely or never
Snacks	How often do you eat in between your regular meals?	Rarely or never
Breakfast	Do you eat breakfast most mornings?	Almost every day

[a]Lubben[29] modified the original Berkman-Syme[14] Social Network Index specifically for use with older populations. Cronbach alpha for the 10 items included in the LSNS was .70.
[b]Due to age of respondents, lower levels of exercise were tolerated than in original Belloc-Breslow study.[5]
[c]The 1960 Metropolitan Life Tables[30] were used to conform with recent NCHS data.[6] The standards were also similar to those used in other studies of elderly persons.[10,31]
[d]Standard suggested by LaCroix, *et al.*[32]

APHA Issues Report on "HIV Antibody Testing"

HIV Antibody Testing—the 4th report of the Special Initiative on AIDS, a program activity of the American Public Health Association—has been released. This new report, prepared by the AIDS Working Group, summarizes the use and the purpose of the human immunodeficiency virus (HIV) antibody tests. The necessary components and considerations of testing programs are reviewed and proposals to screen specific populations are discussed.

To date four reports have been issued in this AIDS Report Series.

- No. 1, *Casual Contact and the Risk of HIV Infections* was released in July 1988
- No. 2, *Contact Tracing and Partner Notification*, November 1988
- No. 3, *Illicit Drug Use and HIV Infection*, January 1989
- No. 4, *HIV Antibody Testing*, April 1989.

Single copies of the various reports are available for $3 each prepaid from APHA Publication Sales, 1015 15th Street, NW, Washington, DC 20005. Bulk rates available on request.

Mechanical Restraints on the Medical Wards: Are Protective Devices Safe?

Richard P. Lofgren, MD, MPH, David S. MacPherson, MD, Rosanne Granieri, MD, Sharon Myllenbeck, RN, and J. Michael Sprafka, PhD, MPH

Abstract: We prospectively identified 102 mechanically restrained hospital patients and determined their hospital course. The cohort was elderly, cognitively impaired with multiple chronic diseases. The in-hospital mortality was 21 percent. Nosocomial infection developed in 12 percent and new pressure sores in 22 percent. Prolonged use of restraints (>4 days) was the strongest independent predictor of nosocomial infection (relative risk 1.8, 95% CI = 1.2, 2.8) and new pressure sores (RR 1.4, 95% CI = 1.1, 1.8) as determined by multiple logistic regression analysis. Patients placed in mechanical restraints for longer than four days experience frequent morbid events and should be monitored carefully. (*Am J Public Health* 1989; 79:735–738.)

Introduction

Mechanically restrained patients are a familiar sight on the medical wards in many hospitals in the United States. A survey of a general hospital found that more than 7 percent of patients admitted to the general medical floors were restrained at some time during their hospital stay.[1] Elderly veterans were found in restraints in 17 percent of admissions to medical wards.[2] By contrast, restraints are used much less frequently in other countries such as the United Kingdom.[3,4]

Posey vests, ankle and wrist restraints are often used to bridle confused patients for the purpose of preventing falls. Between 70 to 80 percent of all inpatient incident reports are related to patient falls.[5–9] Accidents and falls do occur despite the use of these devices.[10] A recent study comparing two Canadian hospitals found that the institution that used restraints less often had about half as many accidents.[3] Little is known about possible complications related to the use of mechanical restraints. Patients have been inadvertently hung and strangled to death trying to escape from restraining devices[11,12] and episodes of hyperpyrexia and rhabdomyolsis have been reported.[13,14]

We prospectively followed a cohort of mechanically restrained patients residing on the general medical service of an acute care hospital to describe the characteristics and clinical outcomes of this population of patients. We further identified risk factors for death, new pressure sores and nosocomial infections.

Methods

We prospectively followed all patients residing on the general medical wards, who were initially placed in mechanical restraints during a 13-week enrollment period. Patients in the intensive care, coronary care, special diagnostic study, and restorative care units were excluded. Mechanically restrained patients were identified by the charge nurse each shift. The protocol was approved by the hospital's human studies committee and informed consent was obtained from each patient or next of kin.

Within 48 hours after patients were first restrained, one of the investigators reviewed the medical record and examined the patient. Data were collected using a standard form. Demographic and clinical data were abstracted from the chart using the housestaff and nursing notes. Administration of medications was determined through nursing records. Resuscitation status was determined through review of orders and housestaff notes. Each patient was examined initially for the presence of pressure sore, incontinence, and indwelling medical devices. A mini-mental status examination was performed,[15] the level of consciousness was estimated, and an assessment of the patient's ambulatory and functional status was determined.[16]

Throughout the hospital stay, the record of each mechanically restrained patient was reviewed every 48 hours and the patient re-examined with attention to nosocomial infections, status of pressure sore, presence of incontinence, and presence of indwelling medical devices. Falls were considered to have occurred if noted by nursing or physician staff or if noted in an incident report form. At discharge, the length of stay and disposition of the patient was noted.

A mechanical restraint was defined as any device applied to a patient for the purpose of limiting free movement, such as a posey vest, wrist restraint, or full sheet restraint. This did not include bed side rails or geri-chairs. Pressure sore was defined as a local area of epidermal defects or necrosis over pressure points or bony prominence ranging from grade I (reactive hyperemia lasting more than 24 hours) to grade V (deep ulceration extending to the bone).[17] A nosocomial infection was defined as one that was neither present nor incubating at the time of the patient's admission and had its onset during hospitalization. New fecal or urinary incontinence was noted if soilage was found on physical examination, a condom or indwelling urinary catheter was present, or a notation by a physican or nurse was found in the record. Infusion thrombophlebitis was considered to be present if two or more of the following signs and symptoms were present: pain, erythema, swelling, induration, or palpable venous cord.

Descriptive statistics were calculated for the cohort of restrained patients. Demographic and clinical characteristics were examined to determine which factors were associated with adverse outcomes, including death, development of pressure sore, nosocomial infection. Stepwise logistic regression analysis was used to determine factors independently and significantly associated with adverse outcomes. Statistical analyses were performed using SPSS[19] and BMDP[20] statistical software.

Results

Of the 1,661 patients admitted to the general medical wards during the study period, 102 (6 percent) were mechan-

This paper, submitted to the Journal July 18, 1988, was revised and accepted for publication February 2, 1989.

ically restrained at some point during their hospital stay. The restrained patients were elderly with an average age of 75.4 years (s.d. = 12.7, range 50 to 98 years). All but one were male. Restrained patients were admitted from home (42 percent), nursing homes (27 percent), transfers from other hospitals (15 percent) or intensive care units (13 percent), or elsewhere (3 percent). Over half of the patients were restrained on the day of admission. The average time from admission to when the patient was first restrained was 1.8 days (range from 0 to 17 days). Patients were entered into the study at the time they were first restrained and observed for the remainder of their hospital stay. The average length of stay in the hospital was 13.4 days (±13.3 days). Posey vests were used in 61 percent of patients, soft wrist restraints in 14 percent, and both in 24 percent.

The clinical characteristics of the restrained cohort are summarized in Table 1. The most common admitting diagnoses fell into three major categories: infectious diseases (25 percent); central nervous system (CNS) disorders (structural or metabolic) (20 percent); and cancer (15 percent). Almost all the patients were cognitively impaired.

Adverse events were common among the restrained patients (Table 2). Nearly 60 percent of the patients admitted from home were discharged to chronic care facilities. Eighty-two different pressure sores were seen in 37 of the 102 mechanically restrained patients; 36 were new sores that developed in 22 of the patients. Four patients developed sores that progressed to grade II or greater. Of the 82 sores visualized, 63 percent were grade I, 29 percent were grade II, and 8 percent grade III. During the course of hospitalization, 23 percent of the pressure sores increased in size, 26 percent decreased or resolved, and 51 percent did not change.

Different demographic and clinical characteristics were analyzed for associations with morbid events (Table 3). Nosocomial infections and new pressure sores were most strongly associated with prolonged use of mechanical restraints (dichotomized by the upper tercile of length of time in restraints; >4 days). In-hospital mortality was associated with a DNR (do not resuscitate) status and nosocomial infection.

Using a logistic regression model, we investigated the extent to which various clinical parameters might affect the probability of an adverse outcome. For each dependent variable, nine independent variables were entered in the model (Table 4). Consistent with the univariate analysis, the length of time restrained was a significant predictor of nosocomial infection and new pressure sores but not of in-hospital mortality.

TABLE 2—Summary of the Clinical Course of the 102 Restrained Patients during Their Hospitalization

Outcome	Percent
Falls	4
New Urinary Incontinence*	29
New Fecal Incontinence*	29
Infusion Thrombophlebitis**	13
New Pressure sore	22
Nosocomial Infection	12
In-Hospital Mortality	21

*This represents percentage of patients who were initially continent who became incontinent after being placed in mechanical restraints.
**105 different intravenous devices were used in this cohort. Twelve were in place >72 hours and there were no cases of septic phlebitis.

To adjust for possible differences in total exposure time (or length of stay) between the patients restrained for more than 4 days (long-time group, N = 35) and those restrained for 4 days or less (short-time group, N = 67), we examined the rate of the morbid events per patient-hospital day. The rate of nosocomial infections and new pressure sores were higher in the long-time versus short-time restrained group: 26 versus 3 nosocomial infections per 1,000 patient-hospital days (95% CI of the difference = 3, 42) and 38 versus 13 new pressure sores per 1,000 patient-hospital days (95% CI of the difference = 1, 49). Consistent with the multivariate analysis, other indirect measures of severity of illness were similar between the two groups including number of chronic diseases, discharge diagnoses, mobility status, DNR status, use of intravenous lines, and foley catheters.

Discussion

Over 6 percent of patients residing on the general medical floors at our institution were restrained at some point during their hospitalization. Mechanically restrained patients were usually elderly and often confused with multiple chronic diseases. Nearly one-half of these patients received some

TABLE 1—Clinical Characteristics of 102 Mechanically Restrained Patients

Underlying Conditions	Mean ± SD	Median	Percent
Number of Chronic Diseases	4.6 (±0.2)		
Number of Discharge Diagnoses	6.8 (±0.3)		
Number of Medications Prescribed at Time of Restraints	4.6 (±0.2)		
Do Not Resuscitate (DNR) Status			57
Use of Centrally Acting Medications*			49
Physical Examination			
Mini-Mental Status Score (median)**		10.8	
Ambulates Independently			13
Pressure sore Present at Time of Restraints			28
Incontinence Prior to Being Restrained			
Urine			46
Fecal			23
Devices Used during Hospitalization			
Foley Catheter			29
Intravenous Lines			63
Nasogastric Tube			12

*The centrally acting medications used in this cohort included narcotics (25%), benzodiazepam (35%), and phenothiazines (19%). Some patients receive more than one of these medications thus the total is >49%. **A mini-mental score of <24 suggests "probable" dementia and a score <15 indicates "definite" dementia. Only 9.8% of the patients had a score >24.

TABLE 3—Clinical Factors Associated with Untoward Outcomes*

Outcome	Parameters	Odds Ratio	95% CI
In-Hospital Mortality	DNR Status	23.3	3.0, 182
	Nosocomial Infection	4.3	1.1, 16.0
New Pressure sore	Length of Time Restained	6.3	2.0, 20.3
	Previous Pressure sore	3.8	1.2, 11.5
	Nosocomial Infection	4.4	1.1, 18.4
	New Fecal Incontinence	2.2	0.7, 7.0
Nosocomial Infection	Length of Time Restained	12.4	2.5, 60.7
	Length of Hospital Stay	7.5	1.6, 36.4
	Nasogastric Tube	4.9	1.2, 20.1
	Intravenous Lines	6.8	0.8, 55.5

*Clinical factors included length of time restrained, length of stay, age, new or previous pressure sore, new or previous fecal incontinence, new or previous urinary incontinence, mini-mental score, ambulation status, DNR status, number of chronic illness, number of discharge diagnoses, number of medications, number of centrally acting medications, condom or foley catheters.

TABLE 4—Significant Predictors of Adverse Outcomes among Mechanically Restrained Patients Using a Logistic Regression Model

Outcome	Predictors	Relative Risk	95% C.I.
In-Hospital Mortality*	DNR Status	53.7	3.0, 956
	Nosocomial infection	26.7	2.6, 268
	No. Chronic Diseases	1.4	0.9, 2.1
Nosocomial Infection**	Length Restrained	1.8	1.2, 2.8
	Mini-Mental Score	1.2	0.9, 1.3
New Pressure Sore†	Length Restrained	1.4	1.1, 1.8
	Age	1.05	0.99, 1.1

*The dependent variables included in this model were length of time restrained, age, mini-mental score, ambulation status, DNR status, number of chronic illness, number of medications, nosocomial infection, use of foley catheters

**The dependent variables included in this model were length of time restrained, age, previous pressure sore, fecal incontinence, mini-mental score, number of chronic illness, number of medications, and use of foley catheters or intravenous lines.

†The dependent variables included in this model were length of time restrained, age, previous pressure sore, new or previous fecal incontinence, new urinary incontinence, mini-mental score, ambulation status, and number of chronic illnesses.

medication that would affect mental capacity. Undesirable clinical outcomes were frequent in this group of patients. The mortality rate of restrained patients was quite high with one of five not surviving hospitalization. Sixty percent of those admitted from home were discharged to a chronic care facility.

The use of mechanical restraints at our institution is similar to other reports. Frengley, *et al*, surveyed all patients admitted to the medical service of a large urban city/county hospital in Cleveland and found that 7.4 percent were restrained.[1] Robbins, *et al*, studied all patients greater than 70 years of age and a random sample of those less than 70 years of age admitted to the Denver VA Hospital and found and that 17 percent were restrained during hospitalization.[2] The incidence of use in our study was lower, in part, because we did not include patients restrained in geri-chairs. Both of the other studies noted an 8- to 12-fold increase in mortality among the restrained population. These studies, however, did not examine other clinical outcomes.

Our cohort of restrained patient suffered extraordinarily high rates of in-hospital death and morbid events (Table 2). Patients restrained for greater than 4 days developed significantly more nosocomial infections and new pressure sores when compared to the group restrained for the shorter period. Using a multiple logistic regression model, the length of time restrained was found to be the only independent predictor of nosocomial infection and new pressure sore. Mortality was unaffected by the duration of restraint.

The increased observed morbidity noted in the long-time restrained group may be due to a difference in severity of illness. However, the clinical characteristics of the two groups were quite similar (Table 3). With our logistic regression model, we attempted to adjust for measures of potential difference in severity of illness (such as the number of discharge diagnoses). Although the groups appeared to be clinically comparable, it is possible that subtle differences still existed.

There are several other potential limitations to this study. The patient population was a homogeneous group of elderly men hospitalized on the general medical wards of a large urban VA medical center and conclusions regarding restraint use must be applied with caution to other clinical situations such as community hospitals, psychiatric units, intensive care units, or extended care facilities. Our cohort study only consisted of patients who were restrained and did not contain a clinically comparable group that was never restrained. We are therefore unable to establish a causal relationship between the use of mechanical restraints and morbid events. To firmly establish a causal relationship, a controlled trial in which eligible patients were randomly assigned to receive mechanical restraints versus some alternative therapy would be necessary. In the meantime, our findings demonstrate an important dose effect; those patients restrained for longer periods of time had more adverse outcomes.

It is not clear why prolonged use of restraints is associated with morbid outcomes. Restraining patients may be a form of medical and social isolation. It is more difficult to turn or examine patients while they are in restraints. Essential patient care procedures may therefore not be routinely

performed. Restraints may cause nurses and physicians to feel patients are unable to communicate. Loss of autonomy and social isolation have been shown to adversely affect the physical and mental health of elderly patients.[21,22] Less intense care and isolation may increase the chance of an adverse event.

The results of our study suggests that mechanically restrained patients need to be closely monitored. If mechanical restraints seem necessary, effort should be made to limit their use to no more than four days. Further investigations are needed to confirm our findings and to identify the reasons that morbid events are increased with the use of restraints. Alternate safety measures, free of associated morbidity, should be developed to protect this vulnerable population.

ACKNOWLEDGMENTS

The authors thank Charles F. Moldow, MD, for his suggestions and guidance, the nursing staff on the medical wards at the Minneapolis Veterans Administration Medical Center and the housestaff of the University of Minnesota Hospitals for their cooperation. This work was presented in part at the 9th annual meeting of the Society of General Internal Medicine (formerly SREPCIM), Washington, DC, May 1986.

Call for Manuscripts on Mentoring, Counseling . . .

The quarterly journal, *Mentoring International*, now in its third year of publication, is actively soliciting manuscripts for future issues. The journal accepts items on the topics of mentoring, coaching, tutoring, sponsorships, counseling, networking, preceptorships, in any field, including nursing, education, business and government, history, at-risk youth, law enforcement, etc. Articles range from scholarly refereed ones to practical applications, book reviews, surveys, case studies, and literature reviews.

Interested contributors should contact the journal directly for guidelines. The deadlines for submission are: September 30, 1989 (February 1990 publication); December 30, 1989 (May 1990 publication); March 30, 1990 (August 1990 publication).

For further information, contact: The Mentoring Institute, Inc., International Center for Mentoring, 510-1200 West Pender Street, Vancouver, British Columbia V6E 2S9. Tel: (604) 684-4134.

Cost-Effectiveness of Antibiotic Prophylaxis for Dental Procedures in Patients with Artificial Joints

JOEL TSEVAT, MD, MPH, ISABELLE DURAND-ZALESKI, MD, MPH, AND STEPHEN G. PAUKER, MD

Abstract: We performed a cost-effectiveness analysis to evaluate whether patients with artificial joints should take penicillin, erythromycin, or no antibiotics before dental procedures. We modeled the risk of anaphylaxis from penicillin, the risks and consequences of an artificial joint infection, and the actual variable costs of hospitalization and antibiotics.

Penicillin prophylaxis is slightly less expensive than erythromycin prophylaxis but is both more expensive and less effective than no prophylaxis. Erythromycin prophylaxis, the most effective, is the most expensive strategy. The marginal cost effectiveness of erythromycin prophylaxis compared to no prophylaxis is $12,900 per quality-adjusted year of life saved. Sensitivity analysis demonstrates that the risk of developing a joint infection is the key parameter in the analysis.

Based on our estimated risk of developing a joint infection, the cost-effectiveness of antibiotic prophylaxis with erythromycin compares favorably with other medical interventions. Thus, until a definitive study to quantify the risk is conducted, patients with artificial joints should take prophylactic erythromycin when they undergo dental procedures. (*Am J Public Health* 1989; 79:739–743.)

Introduction

Antibiotic prophylaxis to prevent bacterial endocarditis is accepted medical practice in patients with valvular heart disease who undergo dental manipulation.[1] Whether or not patients with prosthetic joints should take prophylactic antibiotics to prevent septic arthritis has not been established. Dental infections have been shown to cause septic arthritis in artificial hips via hematogenous spread,[2] but few if any cases of prosthetic joint infections directly attributable to dentally induced transient bacteremias have been reported and confirmed.[3]

Nevertheless, many authorities recommend antibiotic coverage during dental procedures for patients with artificial joints.[4–6] Jaspers and Little found that although only 41 per cent of orthopedic surgeons believed that dentally induced bacteremias could cause prosthetic joint infections, 93 per cent recommended giving antibiotics to their patients.[3]

The scope of the problem is large: in the United States in 1986, there were 201,000 total hip replacements and other hip arthroplasties, 91,000 total knee replacements, and 245,000 other upper and lower extremity arthroplasties and joint replacements—a total of 537,000 arthroplasties.[7] The risks of administering prophylactic antibiotics primarily involve adverse reactions including anaphylaxis. The potential benefits, on the other hand, are infections and hospitalizations averted and lives saved. The issues then are both clinical and economic. We explored these issues in a cost-effectiveness analysis.

Methods

The Decision Model

The problem can be represented as a decision tree (Figure 1). The model encompasses only one visit to the dentist and its consequences. The three branches emanating from the square decision node represent the three strategies we examined: the dentist can prescribe either penicillin or erythromycin or choose to give no prophylaxis. Ensuing events are beyond the dentist's control and are represented as round chance nodes.

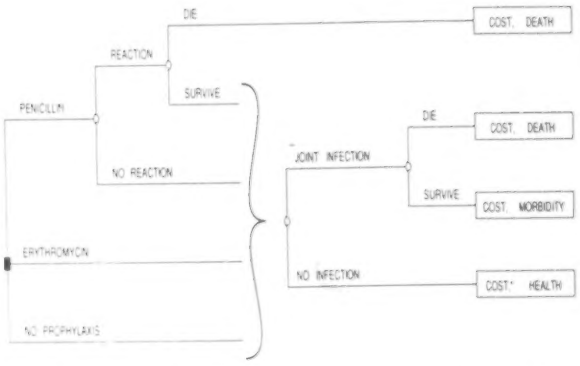

FIGURE 1—The Decision Tree (cost = 0 for the no infection branch of the no prophylaxis strategy)

Assumptions

- Infections resulting from transient bacteremia during dental procedures would be caused exclusively by oral flora, namely by streptococci (including anaerobic streptococci). Therefore, we consider only the 19 per cent of late infections (more than six months postoperative) of hip and knee prostheses caused by *Streptococcus spp*.[4]
- Because there are no data concerning the effectiveness of antibiotics in preventing artificial joint infections resulting from dental procedures, we assume that the effectiveness of prophylactic therapy is the same as for the prevention of bacterial endocarditis in patients with valvular heart disease.
- Because the elderly comprise a large proportion of patients with artificial joints, we derive the probability of developing a joint infection during one visit to the dentist by using the average number of dental visits per year for a cohort of 65-year-olds.
- Only dentulous patients are at risk for transient bacteremias from dental procedures. Consequently,

Pauker, MD, Professor of Medicine, and Chief, Division of Clinical Decision Making, Box 302, New England Medical Center, 750 Washington Street, Boston, MA 02111. Dr. Tsevat is currently with the Division of Clinical Epidemiology and the Division of General Medicine and Primary Care at Beth Israel Hospital, Harvard Medical School. This paper, submitted to the Journal January 19, 1988, was revised and accepted for publication September 22, 1988.

© 1989 American Journal of Public Health 0090-0036/89$1.50

we exclude the 40 per cent of elderly patients who wear dentures from the analysis (Athena Papas, DDS, personal communication).
- Minor medication side-effects (rash and gastrointestinal symptoms) incur no monetary treatment costs but do incur short-term morbidity.

Probabilities

Probability of developing an artificial joint infection from a transient bacteremia during a dental manipulation: The risk for dentulous patients is 9.3×10^{-5} or 9.3/100,000 dental procedures (see Appendix).

Mortality from an infected artificial joint: Little found that 18 per cent of patients with acute dental infections who had hematogenously infected hip prostheses died.[2]

Anaphylactic reactions: The probability of having an anaphylactic reaction to penicillin has been variably estimated to be between 0.0001 (1/10,000)[8] and 0.0004 (1/2,500).[9] In this analysis we use 0.0002 (1/5,000). If one in 50,000 (0.002 per cent) patients taking penicillin has a fatal anaphylactic reaction,[10] then one in 10 patients having an anaphylactic reaction dies.

We assume that erythromycin does not cause anaphylaxis.

Effectiveness of prophylactic antibiotics: The effectiveness of prophylactic penicillin in preventing septic arthritis is defined as:

$$1 - \left(\frac{\text{the probability of developing septic arthritis in a treated patient}}{\text{the probability of developing septic arthritis in an untreated patient}} \right)$$

A recent case-control study[11] found the effectiveness of prophylaxis in patients with valvular heart disease to be 0.91; the study did not differentiate among antibiotic regimens, however. The effectiveness of prophylactic penicillin in preventing bacterial endocarditis in patients undergoing dental procedures has been estimated by a panel of experts[12] to be 90 per cent. The panel estimated the effectiveness of erythromycin to be 75 per cent. We employ those estimates in this analysis.

Utilities

Possible outcomes are **health** (no infection), **death** (from anaphylaxis or joint infection), and **morbidity** from an infection. Outcomes are expressed as "quality-adjusted life expectancy" for a prototypic 65-year-old patient. The unadjusted life expectancy is derived from 1981 US life tables.

Death: Death is assigned a utility of zero.

Health: A year of health is assigned a utility of one full quality-adjusted life year (QALY).

Morbidity from a joint infection: A year during which a patient is hospitalized for an infected artificial joint is assigned a utility of 0.9 quality-adjusted life years.

Short-term morbidity from penicillin and erythromycin prophylaxis: For patients who do not die from a joint infection or from anaphylaxis, we deducted approximately 8 minutes from their quality-adjusted life expectancy for a course of prophylactic antibiotics (see Appendix).

Costs

Because this analysis takes the perspective of a health maintenance organization (HMO), actual costs rather than charges are used.[13] All costs were converted to 1986 dollars using a 5 per cent annual inflation rate. Future costs are not discounted against present costs because "future costs" (costs of treating joint infections) are incurred only a few months after the visit to the dentist.

Cost of antibiotics: The actual acquisition costs to one large metropolitan hospital's pharmacy of six 500-mg penicillin V potassium tablets and six 250-mg tablets of erythromycin are 28 cents and 30 cents, respectively (E Anderson, Jr, MS, personal communication). We used the recommended regimen for patients with cardiac conditions: penicillin V 2.0 g orally one hour before the procedure and 1.0 g orally 6 hours later, or erythromycin 1.0 g orally one hour before followed by 500 mg 6 hours later.[1]

To estimate the total variable cost of the antibiotics, we added a dispensing cost of $3.43, the average of a price bid by a mid-sized pharmacy chain for a contract with an HMO ($3.09 per prescription) and the internal cost to a large HMO with a house pharmacy ($3.76 per prescription) in 1986 (NM Kane, DBA, personal communication).

Cost of artificial joint infections: Based on experience with all patients (six) at our hospital with late infections (beyond the immediate post-operative period) of hip or knee prostheses (October 1, 1984 to September 30, 1986), the mean marginal (variable) cost of hospitalization was $16,000. (The average total cost of hospitalization was $23,000.)

Cost of anaphylaxis: The mean marginal cost of all patients treated for anaphylaxis during the same time period was $1,200 (the mean total cost was $2,900).

Results

No prophylaxis is the least costly strategy; penicillin is the next, being just slightly less expensive than erythromycin. Erythromycin is the most effective strategy followed by no prophylaxis and then penicillin (Table 1). Thus penicillin is both more expensive and less effective than no prophylaxis. The marginal cost-effectiveness of erythromycin compared to no prophylaxis is $12,900 per quality-adjusted year of life saved.

Sensitivity Analyses

We varied each of the probabilities over the full range of possible values and the costs over a wide range (Table 2).

TABLE 1—Baseline Results

Strategy	Cost ($)	Effectiveness (QALY)	Marginal Cost ($)	Marginal Effectiveness (QALY)	Marginal Cost/Effectiveness ($/QALY)

DOM indicates that the particular strategy is dominant (least expensive and most effective)
*Ratios greater than 100 are rounded to the nearest 100
†Value used in baseline analysis
‡Possible values range from 0 (equivalent to death) to 1 (equivalent to health prior to the infection), with intermediate values corresponding to "fractions" of "full health"
¶Excludes dispensing cost

Although the ranking of strategies by cost shifts with minor deviations from the baseline values of many variables, erythromycin tends to remain the most effective. For example, if the actual probability of an artificial joint infection is greater than 27/100,000, penicillin becomes the least expensive strategy; however, it remains less effective than erythromycin unless the risk of infection exceeds 72/100,000. The sensitivity analysis on the probability of joint infection subsumes a sensitivity analysis on the fraction of hematogenous infections caused by transient bacteremias from dental manipulations, assumed in the base case to be 10 per cent. Thus, all other things being equal, if the fraction of hematogenous infections due to dental manipulations exceeds 29 per cent, erythromycin becomes the least expensive strategy, but it remains less effective than erythromycin unless the fraction exceeds 77 per cent.

An important variable is the probability of anaphylaxis from penicillin, because the risk from oral administration may be lower than the published risk[8–10] in which the route of administration was not specified. Even if the incidence of allergic reaction is half as great after oral administration as after parenteral administration,[14] penicillin is less effective than erythromycin and the marginal cost-effectiveness of erythromycin is $12,900 per additional life saved compared to no prophylaxis. Penicillin becomes the most effective strategy (but remains more expensive than no prophylaxis) if the risk of fatal anaphylaxis is less than approximately 1/400,000 (baseline risk: 1/50,000).

The analysis is also very sensitive to outpatient antibiotic *dispensing* costs. If dispensing costs amount to only 20 per cent of acquisition costs (MC Weinstein, PhD, personal communication), or six cents per prescription, then penicillin is the least expensive (and least effective) strategy and the marginal cost-effectiveness of erythromycin compared to penicillin is only $14 per QALY saved. With dispensing costs of $3.76 per prescription, on the other hand, no prophylaxis is the least expensive strategy and the incremental cost of prescribing erythromycin is $14,500 per additional QALY gained.

Discussion

Based on our assumptions, erythromycin prophylaxis for dental procedures in patients with artificial joints seems to be worthwhile. Prophylaxis with penicillin, however, is both more expensive and less effectiveness than no prophylaxis. Several issues merit further consideration.

This cost-effectiveness analysis was performed from the perspective of an HMO. Only hospitalization and drug costs were considered. Because infected patients would have more frequent follow-up visits than the non-infected ones, prophylaxis with erythromycin could appear to be even more cost-effective if one includes the cost of outpatient follow-up. From the patient's perspective, non-medical direct costs (e.g., transportation) and indirect costs (e.g., lost wages) require consideration; including these would also bolster the case for erythromycin.

The cost of *dispensing* antibiotics in the outpatient pharmacy has a major impact on the analysis. In the base case, we assigned a dispensing cost ($3.43 per prescription) that exceeds the acquisition cost by over 1000 per cent! Perhaps the average dispensing cost exaggerates the cost of dispensing only six tablets, and a fixed fraction (e.g., 20 or 40 per cent) of the acquisition cost might be more appropriate. There is an opportunity cost to filling inexpensive prescriptions, however, and time spent filling an inexpensive prescription could have been spent filling a more expensive prescription. From an opportunity cost standpoint then, perhaps the real cost of dispensing the antibiotic is about $3.43. If so, the no prophylaxis strategy is the least expensive because dispensing costs dominate the costs of treating joint infections.

The costs of each strategy can be broken into their components (Table 3). In the no prophylaxis strategy, drug and anaphylaxis costs are zero; the entire cost consists of infection costs. In the erythromycin and penicillin strategies, drug costs dominate anaphylaxis and infection costs.

There is a trade-off between the two antibiotics. Penicillin is slightly less expensive whereas erythromycin is slightly more effective because it carries no risk of anaphylaxis. If the dentist is *absolutely certain* that the patient is not allergic to penicillin, then penicillin prophylaxis would be both less expensive and more effective than erythromycin and the marginal cost-effectiveness of penicillin compared to no prophylaxis would be $9,100 per QALY saved (analysis not shown).

Two published analyses have addressed the issue of endocarditis prophylaxis for dental procedures in patients with mitral valve prolapse. Bor and Himmelstein[12] concluded that no prophylaxis or prophylaxis with erythromycin is preferable to prophylaxis with a combination of parenteral and enteral penicillin because the number of deaths from penicillin reactions far outweighs the number of deaths from endocarditis that would be prevented by penicillin prophylaxis. Clemens and Ransohoff[15] found that the risks of parenteral penicillin outweigh the benefits; in addition, they concluded that oral penicillin prophylaxis spares life only in older adults with mitral valve prolapse, at a cost of $2.6 million per case of endocarditis prevented ($1.3 million per year of life saved).

Our analysis arrives at similar conclusions despite a major difference in the risk of infection. The other analyses estimated the risk of endocarditis to be 4.1–4.9 cases per million dental procedures.[12,15] In this analysis, the risk of septic arthritis was estimated to be 93 per million dental procedures. Their estimates were based on reported cases; our estimate was based on a cohort study.[16] If these infection rates are accurate, then we would expect to see more cases of endocarditis in patients with mitral valve prolapse after dental procedures than we see septic arthritis in patients with artificial joints only because mitral valve prolapse is much more prevalent than are prosthetic joints.

The derived probability of developing a joint infection rests on tenuous data and assumptions, including the probability of seeding a joint, the number of edentulous 65-year-olds, the frequency with which dentulous and edentulous patients see a dentist, etc. The sensitivity analysis of the probability of developing a joint infection (Table 2) encom-

TABLE 3—Per Capita Component Costs of Each Strategy

Component	Strategy		
	No Prophylaxis	Erythromycin	Penicillin
Antibiotics	$0.00	$3.73	$3.71
Anaphylaxis	$0.00	$0.00	$0.24
Joint infections	$1.49	$0.37	$0.15
Total	$1.49	$4.10	$4.09*

*Total differs from sum of components due to rounding

passes sensitivity analyses on each of those assumptions and probabilities. Central to this analysis, of course, is the assumption that a transient bacteremia during a routine dental procedure *can* cause an infection of prosthetic joint. Ideally, we could answer this question with a clinical trial or case-control study. Until that time, we rely on assumptions and previous studies and conclude that, from a patient's perspective, the benefits of taking prophylactic erythromycin prior to dental procedures outweigh the risks. Moreover, the cost to a payor per quality-adjusted year of life saved is relatively low, being comparable in a cost-effectiveness to estrogen therapy in the menopause,[17] treatment of mild hypertension,[18] and dietary treatment of hypercholesterolemia[19] (analyses done from a societal perspective).

APPENDIX

Probability of Developing an Artificial Joint Infection from a Transient Bacteremia During a Dental Manipulation

Ahlberg and colleagues[16] found that 0.29 per cent of patients with artificial joints developed hematogenous infections over an eight-year period (average length of follow-up not given). But only a portion of hematogenous infections, 10 per cent in Little's estimate,[2] are caused by transient bacteremias from dental manipulations. Knowing these values, the number of dental visits per year in the 65-year-old age cohort (1.3 visits per person per year),[20] and the percentage of these patients who do not wear dentures (and thus are at risk for seeding the joint), one can estimate a probability of a joint infection in the following manner:

Assuming that the *average* length of follow-up in Ahlberg's series was four years, we divide 0.0029 by 4 to get a rate of 7.3×10^{-4} hematogenous infections per patient per year. Because each patient, on average, sees the dentist 1.3 times each year, the rate of hematogenous infections per visit is 5.6×10^{-4}. Assuming only 10 per cent of hematogenous infections are caused by transient bacteremias from dental manipulations, we deduce the probability of developing a joint infection from a transient bacteremia in the dentist's chair to be 5.6×10^{-5}. This is the cumulative population risk; but this risk is borne only by the 60 per cent of patients who are dentulous. Thus the risk among dentulous patients is 9.3×10^{-5} or 9.3 per 100,000 dental procedures. Note that this risk may well be a lower bound because some of the patients in Ahlberg's series may have received prophylactic antibiotics and because his criteria for joint infection may have omitted indolent cases.

Short-term Morbidity from Taking Penicillin

Approximately 5 per cent of patients taking penicillin develop a hypersensitivity reaction, most commonly a rash.[21] We assumed that rash would last 48 hours, during which quality of life would be 95 per cent of baseline quality. To calculate the average disutility per patient, we multiplied the fraction of patients affected (0.05) by the product of the duration (48 hours) and disutility (1–0.95); the result is not if 7.5 minutes, which we deducted from the patient's life expectancy.

Short-term Morbidity from Taking Erythromycin

Here, we assumed that approximately 75 per cent of patients would suffer gastrointestinal side effects[22] lasting three to four hours, and that their quality of life during that time would be 95 per cent of baseline. The net average disutility is again 7.5 minutes per patient.

ACKNOWLEDGMENTS

The authors would like to thank Ross Shachter, PhD, for his help in deriving the probability of developing septic arthritis, and Gertrude Kramer, MD, for originally asking us to perform a clinical decision analysis for one of her patients. This research was supported in part by training grant LM 7044 from the Medical Informatics Program, National Library of Medicine, Bethesda, MD.

Physical Activity and Risk of Cancer in the NHANES I Population

Demetrius Albanes, MD, Aaron Blair, PhD, and Philip R. Taylor, MD, DSc

Abstract: We studied the relation between self-reported physical activity and cancer in the first National Health and Nutrition Examination Survey (NHANES I) cohort, originally examined between 1971–75, and followed prospectively through the Epidemiologic Follow-up Study (NHEFS), conducted between 1982–84. Among 5,138 men and 7,407 women 25–74 years old, for nonrecreational activity we observed increased risk of cancer among inactive individuals compared to very active persons (for men, relative risk [RR] 1.8, 95% confidence interval [CI] = 1.4, 2.4; for women RR 1.3, 95% CI = 1.0, 1.8). These findings were unchanged after adjustment for cigarette smoking, body mass index (BMI), and other potential confounders. Sites which demonstrated stronger inactivity-cancer associations included colorectum (RR 1.6,95% CI = 0.7, 3.5) and lung (RR 1.6; 95% CI = 1.2, 3.5) among men, and breast (postmenopausal) (RR 1.7; 95% CI = 0.8, 2.9) and cervix (RR 5.2; 95% CI = 1.4, 14.5) among women, although these findings for women were based on relatively few cases. The association between inactivity and cancer was greater among persons of moderate (or lower) BMI, those cases occurring three or more years after baseline, and, in women, those more than 60 years old. In contrast, recreational exercise showed little relation to cancer, with the exception of prostate cancer. The results suggest that inactive individuals are at increased risk of cancer. (*Am J Public Health* 1989; 79:744–750.)

Introduction

The beneficial effects of physical activity on cardiovascular disease risk have been well documented.[1] Persons with other chronic illnesses such as osteoporosis and diabetes mellitus have likewise shown improved clinical status while on exercise regimens.[2,3] To a lesser degree, physical activity has also been studied with respect to risk of cancer. Early studies provided evidence for an inactivity-cancer relation,[4–6] but there have been conflicting data.[7,8] More recently, a population-based study of men[9] demonstrated an inverse association between incidence of colon cancer and level of occupational physical activity, which was corroborated by two subsequent reports.[10,11] Although these studies, and one of female cancers among former college athletes,[12] support the notion that greater physical activity is associated with reduced cancer risk, they have been limited to group estimates of physical activity based upon occupational classification or athletic status.

We examined the relation between self-reported activity level and the subsequent development of cancer in a large cohort of US men and women. The present investigation extends previous research by assessing the role of both recreational and nonrecreational physical activity, by evaluating relative body weight and other potential confounders of the activity-cancer association, and by including men and women.

Methods

We analyzed data available on public use tapes from the first US National Health and Nutrition Examination Survey (NHANES I) and the NHANES I Epidemiologic Follow-up Study (NHEFS). Details of their design have been presented elsewhere.[13,14] Between 1971 and 1975, 14,407 men and women ages 25–74 participated in NHANES I which was conducted by the National Center for Health Statistics (NCHS) and was designed to characterize a variety of health and nutrition-related parameters in a representative sample of the U.S. civilian population. Of the participants, 12,554 (87 per cent) were successfully traced and reinterviewed (14 per cent by proxy) during the period 1982–84 by NCHS as part of the NHEFS. All persons for whom baseline data existed concerning age, physical activity, stature and body weight, and who were without cancer at study entry (35 prevalent cases were identified through the baseline medical history interview and hospital records) were included in this investigation. Thus, the analytic cohort was comprised of 5,141 men (41 per cent) and 7,413 women (59 per cent), of whom 84 per cent were White. The median age at study entry was 48 years for women and 52 years for men.

Incident cases of cancer (excluding nonmelanoma skin cancer), confirmed through hospital record or death certificate review, served as endpoints for this study. Pathology reports were obtained for all cases. During the follow-up period (median length 10 years), 460 cancers developed among men (including 114 lung, 95 prostate, and 62 colorectum), and 399 among women (122 breast and 67 colorectum). Because relatively few cases (i.e., <35) occurred for specific cancer sites other than lung, prostate and colorectum in men, and breast and colorectum in women, they were not initially analyzed separately. Similarly, cancer of the colon and rectum were left combined because of very small case numbers (for men and women, respectively: colon, 36 and 48; rectum, 26 and 18), and the lack of any material difference between their respective associations with activity.

Two questions concerning physical activity were asked during the baseline evaluation. The first, dealing with nonrecreational activity, was: "In your usual day, aside from recreation, how active are you?" The possible responses were: "very active", "moderately active", or "quite inactive". The second question ("recreational exercise") asked: "Do you get much exercise in things you do for recreation?" "Much exercise", "moderate exercise", or "little or no exercise" were the available responses. Information concerning potential confounding risk factors was also obtained. Height and weight were measured at baseline using standard methods,[15] and the body mass index (BMI, weight (kg)/height $(m)^2$) was used as a measure of relative body fatness. Race was classified as White, Black, or other at baseline; because there were relatively few persons in the latter two categories, they were combined (i.e., non-Whites) for the present investigation. Maximum education attained was queried in the

baseline interview, and relative economic status was estimated through the use of the NHANES I poverty index ratio, a measure of adjusted family income which compares a person's income, residence, and family size to the poverty level. Cigarette smoking status (never, former, current) and total pack-years were derived from either the baseline interview, or at follow-up interview. Pack-years was the product of the duration of smoking (in years) and the usual number of cigarettes smoked daily (divided by 20). Reproductive and gynecologic history (age of menarche, menopausal status, parity, and age at first live birth) and family history of breast cancer came from both baseline and follow-up interviews. Self-reported employment status, general health ("excellent" to "poor"), and history of a recent hospitalization (during the past year) were obtained at baseline, as was dietary energy and total fat intake information derived from a 24-hour recall questionnaire.

Relative risk estimates were computed using the proportional hazards model of SAS (PHGLM) in which incident cases of cancer served as study events.[16,17] Indicator variables were used for the two lower physical activity levels, leaving persons in the highest activity category as the reference group for both recreational and nonrecreational activity analyses. Age was included in all models as an independent, continuous variable. As indicated in the text, some analyses included adjustment (using indicator variables) for cigarette smoking status and pack-year history, economic status (using the poverty index ratio), reproductive and family breast cancer history, BMI, or dietary fat or energy intake, and for these analyses persons with missing data were excluded. In order to assess the potential impact of early stage, undiagnosed cancer on the physical activity-cancer relationship, we conducted stratified analyses based on length of follow-up i.e., <3 years versus ≥ 3 years. For the later follow-up period, cancers occurring within three years of study entry were excluded. Because none of the factors was found to be a significant confounder in these data, and covariate information was not available for all cases and noncases, only age-adjusted relative risks are presented in the Tables. Trend tests were based on the significance of a model trend variable for activity (scored 0,1,2).

Results

Baseline characteristics of the study participants according to type and level of activity appear in Table 1. Most of the men and women participating in the study reported being either very active or moderately active in their nonrecreational activity, with only approximately 10 per cent being inactive. In contrast, over one-third of the men and nearly half of the women received little or no exercise in their recreational activities. Individuals reporting more daily activity or exercise tended to be younger and of lower BMI (the latter, primarily in women), while the least active persons were in general more likely to be other than White, less educated, and somewhat shorter in stature. One interesting exception concerns the smaller proportion of nonrecreationally very active men (17.7 per cent) with any education beyond high school compared with less active men. Energy intake was directly related to both types of activity, particularly among men, who also exhibited a much greater range in kilocalorie intake across activity categories.

Age-adjusted relative risk of cancer (all sites) was inversely related to nonrecreational physical activity level among men, demonstrating a nearly two-fold risk increase in the inactive group (Table 2). The increase in risk was smaller among women. Among men, the inverse association with nonrecreational activity was strongest for lung cancer, although it was also suggested for colorectal and prostate cancer. There was no similar association for either colorectal or breast cancer in women. Among inactive women, when breast cancer was analyzed according to menopausal status, an inverse association was seen in postmenopausal women [relative risk (CI) among the least active of 1.5 (0.7, 2.8)], while a direct association was suggested for premenopausal women [relative risk (CI) of 0.4 (0.1, 1.8) based on 46 cases]. In addition, there was an increase in risk for cancer of the cervix (n = 20 cases) by decreasing activity levels [relative risk (CI) = 1.0, 2.3 (0.7, 7.2), and 5.2 (1.4, 14.5)].

The findings concerning recreational activity were generally less impressive than for nonrecreational activity (Table 2). The risk of prostate cancer increased with decreasing levels of exercise, and there was a small, nonsignificant increase in risk of colorectal cancer among women receiving moderate or less exercise. Similar to the findings for nonrecreational activity, there was a suggestion of increased risk of breast cancer among postmenopausal women in the low exercise group [relative risk (CI) = 1.7 (0.8, 2.9)], with an

opposite association premenopausally [relative risk (CI) = 0.6 (0.3, 1.2)].

Adjustment for potential confounding risk factors [race, economic and smoking status, BMI, and energy intake (all sites); BMI and dietary fat intake (colorectum); smoking status and cigarette pack-year history (lung); age at menarche and menopause, parity, age at first birth, as well as family history of breast cancer, BMI (or stature), and dietary fat intake (breast cancer); economic status (cervix)] did not materially alter any of the findings concerning either activity type.* For example, the multivariate adjusted relative risk of all sites cancer remained unchanged: 1.0, 1.1, 1.8 for the decreasing levels of nonrecreational activity in men; 1.0, 1.1, 1.2 for women. Similarly, the results were not affected by adjustment for employment status (working versus not) or general health status (subjective report of health or a hospitalization in the past year).

Table 3 shows that compared to persons who claimed to be both very active and exercised, it was generally only those reporting being less active who were at increased cancer risk. (Cancer incidence (per 100,000 person-years) for the reference category was 817 for men and 560 for women.) Joint classification for nonrecreational activity and exercise therefore yielded relative risk estimates comparable to those for nonrecreational activity alone, without evidence of synergism.

Because many of the above results implicated nonrecreational inactivity specifically as a cancer risk factor, stratified analyses for age, BMI, and follow-up time (factors possibly related to inactivity) were conducted and are shown in Tables 4 and 5. In addition, Whites and all others were analyzed separately (Table 4). The risk increase associated with diminished activity was observed in both younger (25–59 years of age) and older men regardless of race (Table 4).

The association was restricted, however, to older women who were not White, and to low and moderate relative weight men and women, with a three-fold risk increase among inactive lean men compared to very active lean men. While length of follow-up did not affect the inactivity-cancer association in women, a somewhat stronger inverse relation was seen among men for cancers occurring three or more years after baseline.

Additional evidence for effect modification by age and BMI appears in Table 5. There was an inverse cancer-activity association only among younger and older men who were of average BMI or less, and in younger, heavier men. Among women, an effect was observed only for the older and leaner category.

The combined effects of race and either age or BMI were also evaluated. Among men, a somewhat stronger association between inactivity and cancer was observed in younger (versus older) Whites, and in other than older White women (Table 6). In both race groups, the association was essentially restricted to those in the lower BMI category. Adjustment for cigarette smoking did not alter the latter finding. Table 7 shows that the inverse activity-cancer association was evident primarily among non-White women, of either age group, and women of lower BMI.

Discussion

Most previous investigations of this area have examined either occupational history or involvement in athletics. Several studies demonstrate an inverse association between occupational physical activity, based on job classification, and the development of malignancy.[4,6,9–11] Siversten and Dahlstrom,[4] in a historically interesting report, showed that the death rate from carcinoma was higher among the unemployed, and inversely related to estimated occupational "muscular activity." The authors attributed their observations to metabolic products of deficient muscular activity which altered body fluids and, therefore, adult epithelial tissue. The effect of age and the tendency for ill individuals to be unemployed or reduce their activity were not, however, adequately addressed. Among railroad workers, Taylor[6] demonstrated approximately one-third lower cancer death rates for "section men" (those involved in heavy manual

labor) compared to less active clerks and switchmen. In three more recent studies,[9–11] the risk of colon cancer was increased by between 30 and 100 per cent among men employed in sedentary occupations. Garabrant, *et al*,[9] suggested that reduced stimulation of colonic peristalsis among those least active could account for the association.

All of the above investigations involved working men, and utilized estimated physical activity based on occupational categories. Our demonstration of a nearly two-fold risk increase among inactive men relative to those more active is consistent with these previous studies, both in terms of the magnitude of the association and the specific implication of inactivity or "sedentariness". The present findings concerning nonrecreational activity are also consistent with the specific association most recently reported[9–11] between colon cancer in men and occupational inactivity. In our study, however, the relation exists for cancer of the rectum as well, but was not observed in women. Nonrecreational activity was positively related to employment in the present data: 79 per cent of the "very active" men were employed compared with only 67 and 51 per cent of the moderately active and inactive men, respectively (49, 39, and 35 per cent for women in the same activity categories). Conversely, only 7 per cent of men with jobs reported being inactive, compared with 19 per cent of the unemployed men. These apparent similarities notwithstanding, our study demonstrated an activity-cancer association which is independent of employment status, since adjustment for this factor did not affect our results, and the nonrecreational activity association was observed in both the employed and unemployed (data not presented). Therefore, while inactive persons were less likely to be working, it was not their lack of work which increased their risk of cancer.

The study of athletes, another approach to investigating the relation between cancer and physical activity (or more specifically, fitness) has yielded conflicting data.[5,7,8,12] Two early studies[5,7] lacked control groups, and may have suffered both from biased samples and inadequate consideration of age. A retrospective cohort study based on death certificates and athletic status in college showed a small excess of age-stratified (by 10-year birth cohorts) cancer mortality, particularly for cancer of the prostate, among Harvard "letter men" (varsity athletes) compared to either athletes not having received a "letter", or to students who had applied for (but did not receive) a gymnasium locker.[8] The authors could not rule out other confounding effects such as smoking or body size, however. In a similar investigation, female college alumni who had actively participated in one or more team sports during college reported less subsequent cancer of the breast, uterus (including cervix), and ovary than did nonathlete alumni.[12] This association, which persisted after adjust-

ment for several breast cancer risk factors, was evident primarily in women 50–70 years old. However, the number of cancers was small (69 breast, 37 all others combined). One other recent report demonstrated a direct relation between heart rate and total cancer mortality that was unchanged after adjustment for several factors.[18] The authors interpret their findings in light of theories concerning adrenergic activity and psychological stress, although they do not exclude the effects of habitual exercise or sedentary life-style. Interestingly, two sites showing a strong, positive association in this study were lung and colon (a finding similar to ours) but only for the latter site did it remain significant after adjustment for smoking and serum cholesterol.

We demonstrated a positive association with recreational exercise only for prostate cancer, a finding opposite that observed among Harvard athletes.[8] The suggestion of decreased breast cancer risk among postmenopausal women receiving much exercise in our study is consistent with the study of female college athletes mentioned.[12] In that investigation, earlier athletic status provided some risk reduction in the postmenopausal age range only, with no demonstrable athlete-nonathlete difference premenopausally. We did observe increased risk for the high exercise category among premenopausal women. Also, data for cancer of the cervix and endometrium (not shown) are suggestive of a protective effect for a high level of exercise, similar to that observed previously for female athletes,[12] and not accounted for by race, economic status, or body mass index. Unfortunately, the number of cases does not permit a more detailed evaluation of these associations in women, which must therefore remain tentative until investigated by others. The latter associations notwithstanding, given the positive findings for nonrecreational activity, the lack of a stronger overall association for exercise in the present investigation is somewhat surprising. It is possible that the effects of recreational activity are diminished because the duration of daily exercise (and hence its potential influence on disease) is generally much shorter than either athletic training or work-related activity. Alternatively, the observed association for nonrecreational activity may be unrelated to physical fitness; the implication of inactivity *per se* could be interpreted as being supportive of this. It has already been pointed out that the two questions used in the NHANES surveys reflect different aspects of daily activity.[19] Interestingly, we did find that the relation between cancer and nonrecreational inactivity was suggested at all levels of reported daily exercise in men, and for the moderate and little or no exercise groups in women.

The implication of inactivity as a risk factor also suggested to us a possible role for characteristics or illnesses which would both reduce activity and predispose to the development of cancer. Although the appearance of a somewhat stronger inactivity-cancer association among leaner individuals and older women could be interpreted as supporting such a role, several of our findings argue against confounding by prior illness or infirmity. The activity association was observed among: 1) those followed for at least three years before developing cancer (in men, the association was even greater in this subgroup); 2) younger as well as older men; 3) the actively employed (excluding the unemployed and homemakers); 4) nonsmokers; and, possibly most importantly, 5) persons reporting good or excellent general health as well as those denying any hospitalization during the year preceding study entry (data not shown). Thus, it is unlikely that ill health could account for our findings.

The present investigation is unique in the collection of self-reported information concerning daily nonrecreational activity and physical exercise. Such data offer the advantage of individual estimates which may be more specific than job categories or athletic status decades earlier. While an effect from the subjective interpretation of the interview questions cannot be excluded, misclassification from this should only have caused our risk estimates to be reduced. It is noteworthy that we demonstrated increased cancer risk among inactive individuals in spite of this. One level of validation of the NHANES I activity classification is afforded by the caloric intake data which are available. Both age-adjusted mean energy intake (Table 1) and energy not used for resting metabolic rate (RMR) (energy intake minus predicted RMR,[20] a crude estimate of physical activity energy expenditure) increased with activity level. Furthermore, as already discussed, nonrecreational activity was positively related to employment status. Therefore, while direct validation of activity was not feasible in the present study, these indirect data support the value of the self-reports.

In contrast to (and an advantage over) most previous studies, the potential confounding effects of several relevant factors were also evaluated in the present investigation. We observed only relatively weak and inconsistent relations between activity level and most factors studied, and there was no evidence for confounding. Residual confounding due to factors we could not evaluate remains possible, however. It has been suggested that BMI has this potential, especially with respect to colon cancer.[21] While increased BMI is a risk factor for selected sites (including colon) in this cohort,** we observed little change to the relative risk estimates for activity groups upon adjustment for BMI. A stronger inactivity-cancer association was evident primarily among low or moderate BMI individuals for both men and women, particularly among non-Whites. Relative body mass may therefore modify either the effect or level of activity. That is, leanness may be necessary for activity to affect the development of cancer; for example, through an altered metabolic characteristic. Alternatively, it may only be leaner individuals who are active enough to achieve the protective influence, or who more accurately classify their activity level and afford a better test of the hypothesis.

Studies providing more detailed assessment of individual physical activity, and which include women, are needed. Research aimed at elucidating the relevant mechanism(s) would also be useful.

International Conference on Emergency Health Care Development Invites Papers

The International Conference on Emergency Health Care Development, to be held August 15–18, 1989 at the Hyatt-Regency Hotel, Crystal City at National Airport, in the Washington, DC metropolitan area, invites interested persons to submit abstracts on work related to emergency and disaster health care development. Topics on organization, administration, and management will be considered. The conference is intended to serve as a forum and training ground for fostering the discussion of methods for improving emergency health care worldwide.

Attendees wishing to present papers or studies must admit an abstract on the form provided by the conference organizer. To obtain an abstract form, instructions, and a preliminary agenda, contact Medical Care Development International (MCDI), Conference Organizer, 1742 R Street, NW, Washington, DC 20009, telephone: 202/462-1920. Abstracts must be received by June 15, 1989 to be considered for the conference agenda. To speed receipt, prospective participants are encouraged to send a copy of the abstract by telefax in care of MCDI, 202/265-4078, at the same time the original is mailed.

The conference will focus on the development of emergency health care systems, both pre-hospital and in-hospital health care services that respond to sudden illness or injury. The objectives of the international conference are to:

- Clarify the linkages between emergency health care, local and national health care services, and national disaster management systems;
- Present concrete methods for developing or improving emergency health care and disaster response management capabilities within societies which differ widely in resources and characteristics;
- Demonstrate processes by which different emergency health care services have been developed; and
- Propose international emergency health care development goals for the next decade.

The conference agenda is designed to permit special interest tracks, including: Training/Education, Management, Primary Health Care, Disaster Preparedness/Response, and Injury Control/Accident Prevention.

Conference sponsors include: US Department of Health and Human Services, Public Health Service, Health Resources and Services Administration; US Department of Transportation, National Highway Traffic Safety Administration; and the World Health Organization/Pan American Health Organization; in collaboration with United Nations Children's Fund and United Nations Disaster Relief Office.

Ethnic Variation in Cholecystectomy Rates and Outcomes, Manitoba, Canada, 1972–84

MARSHA M. COHEN, MD, T. KUE YOUNG, MD, AND KAREN M. HAMMARSTRAND, MA

Abstract: We used population-based data from the Province of Manitoba's universal health insurance plan to compare the cholecystectomy experience of Native Americans and non-Natives from 1972 to 1984. The age-adjusted cholecystectomy rates for Native females were higher than for non-Native females with the peak rate occurring at age 30–39 for Native Americans and at age 60–69 for non-Natives. The rates for males were three times lower than for females and did not differ between Natives and non-Natives. Native Americans were more likely readmitted to hospital for surgical complications than non-Natives and this held true after controlling for age, sex, rural versus urban residence, teaching versus non-teaching hospital, multiple discharge diagnoses or complex versus simple cholecystectomy (relative odds 1.46, 95 per cent confidence interval 1.17, 1.18). The explanation for the relatively high rates of cholecystectomy among Native American females may be related to high rates of known risk factors for gallstone disease (such as obesity and high parity). However, the higher rates of surgical complications require further study. (*Am J Public Health* 1989; 79:751–755.)

Introduction

A high prevalence of gallbladder disease has been demonstrated in several North American Indian tribes, such as the Pima in Arizona,[1] the Chippewa in north Minnesota,[2] and the Micmac in Nova Scotia.[3] There is speculation that the rise in gallbladder disease among Native Americans constitutes a "New World Syndrome" of metabolic diseases which includes also obesity and diabetes, probably with a common genetic and environmental basis.[4]

While the occurrence of gallbladder disease among Native Americans has been well studied, the rates and outcomes of its surgical treatment among these groups have received limited attention.[5,6] In Manitoba, the existence of population-based data on all health service utilization under the province's universal health insurance plan provides an opportunity to examine the cholecystectomy experience of all residents since the 1970s, and to compare rates and outcomes between Native Americans and the rest of the population.

Methods

For residents of the Province of Manitoba (population about one million, about 50 per cent urban, 50 per cent rural), all physician and hospital care is covered by the Manitoba Health Services Commission (MHSC). Records of health care utilization are routinely filed with the MHSC and, since there are no premiums or user charges, the health insurance claims are known to be complete and highly reliable for the study of surgical rates.[7] Manitoba hospital claims correspond closely to the hospital medical record as to the date of surgery, major surgical procedures performed, and important diagnoses. Record linkage is possible using masked numerical identifiers since neither names nor addresses are released to the researchers. In addition, the MHSC also maintains a continuously updated population-based registry (census) of all residents eligible for inclusion in the plan.

For this study, all hospital records containing a procedure code for gallbladder surgery for the years 1972–78 (ICD-8 codes 43.0–43.9), and for 1979–84 (ICD-9 codes 50.1–51.99) were selected. Status Native Americans were identifiable from special residence codes. This code, however, did not include non-Status Native Americans or Metis. This determination of Indian status in Canada is legalistic and complex, based on the Indian Act. Metis is a distinct cultural group composed of descendants of mixed Native-White marriages during the early settlement of the Canadian West. The US practice of designating people of aboriginal descent with "blood quantum" is not used in Canada. However, because Natives constitute less than 5 per cent of the provincial population, the cholecystectomy rates for the rest of the population would be only slightly overestimated by including the non-Status groups. Data available for each case included demographic information, diagnoses associated with the admission (up to eight diagnoses are recorded), specialty of the surgeon (1972–78 only), and type of hospital (urban teaching, urban non-teaching, rural large, rural small).

From these computer files, we determined the number of cases by age, sex, type of hospital where surgery had taken place, specialty of the attending surgeon, and region of residence within the province (1979–84 only). Using population counts from the MHSC, we next determined the age-adjusted cholecystectomy rate (by the direct method with the 1981 total provincial population as the standard) and the age-specific rates for males, females, Native and non-Natives. The denominators for these rates were obtained from the MHSC registry. Many of the analyses were divided into two time periods 1972–78 and 1979–84 to correspond to the eighth and ninth revisions of the International Classification of Diseases in use at the time and to examine time trends.

Since deaths from cholecystectomy or gallstone disease are rare, (in Manitoba, 0.7 per cent up to two years after surgery[8]), we used readmissions after surgery as the measure of morbidity associated with cholecystectomy. This method involved computer linkage of the original surgical event with subsequent hospitalizations due to known complications associated with the original surgical procedure.[9] In brief, specialist physician panels judged all readmissions to hospital after cholecystectomy and determined which were related to the original surgery. Computer algorithms using diagnostic codes were then developed based upon the physicians' judgments. Agreement between the computer algorithms and the physicians' judgments was very high.[9] A list of the

reasons for readmission up to 120 days which are included in the study is found in the Appendix.

In order to determine which factors might be associated with the risk of readmission, we performed a multiple logistic regression[10] which included age, sex, type of hospital, urban versus rural residence, and whether the original surgery was a simple or a complicated cholecystectomy; as a case-mix measure, we used the number of admission diagnoses associated with the original surgical admission.[11]

Results

Demographic and medical care characteristics of the cases by time period and Native status are seen in Table 1. In both periods the Native population was younger than the rest of the population and included proportionally more women. The majority of Native cases were operated upon in non-teaching hospitals, most of which were in rural areas in contrast to the rest of the population. Data on specialists were only available for the earlier time period. Native Americans were more likely to have received their operation from a rural general practitioner (34.2 per cent) than the rest of the population (18 per cent). In keeping with the distribution of the population of the province, the Native groups were much more likely to live in the north.

The total age-adjusted rate of cholecystectomy over time by sex and Native status is seen in Figure 1. Not surprisingly, the rate for females was about three times higher than that for males. For non-Native females, the rate of operation fell markedly over time. However for Native women, the rates remained high over the 13 years. For males, the rates for non-Natives fell slightly but rose somewhat for Natives. The age-specific rates for Native females peaked at ages 40–49 in 1972–78 and at ages 30–39 for 1979–84 (Figure 2) while for other females, the peak rates were at ages 60–69. The rates for Native females were higher than those for other females except among the elderly. For males, the highest age-specific rates were seen at ages 70–79 for both racial groups (Figure 3).

Table 2 shows the proportion of cases who had readmissions following surgery for the two time periods. Native Americans were more likely to be readmitted to hospital and were more likely to have multiple admissions. In the second time period, Native Americans were still more likely to be

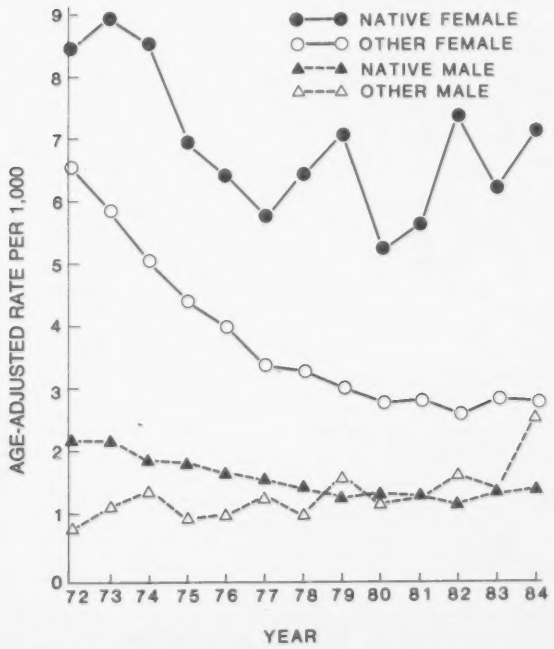

FIGURE 1—Age-adjusted Cholecystectomy Rate per 1,000 Population 1972–84 by Native Status and Gender, Manitoba, Canada

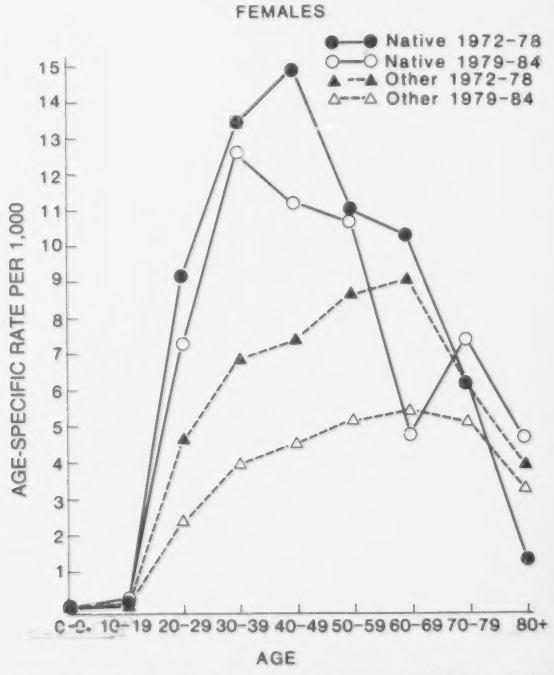

FIGURE 2—Age-specific Cholecystectomy Rate per 1,000 Females, by Native Status and Time Period (1972–78, 1979–84), Manitoba, Canada

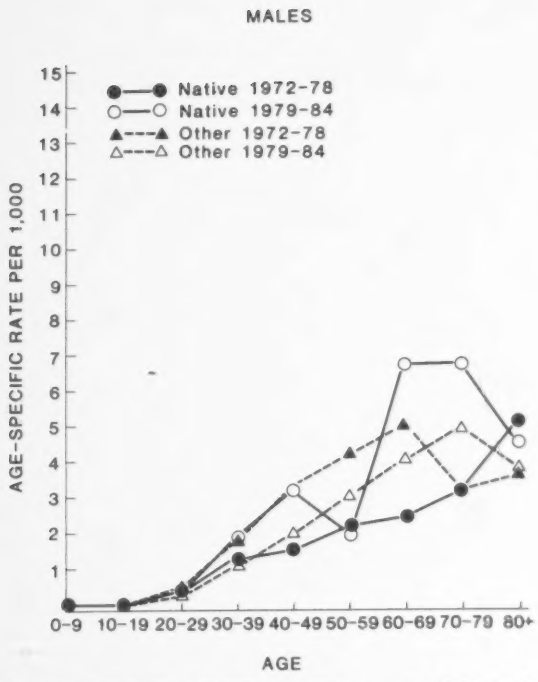

FIGURE 3—Age-specific Cholecystectomy Rate per 1,000 Males, by Native Status and Time Periods (1972–78, 1979–84), Manitoba, Canada.

readmitted than the rest of the population but the proportion of Natives having a readmission fell from 11.9 per cent to 7.8 per cent.

The results of the multiple logistic regression are seen in Table 3. Advancing age was associated with an increased risk of readmission to hospital for a surgically related complication. Females were less likely than males to be readmitted. Patients living in rural areas were more likely to be readmitted to hospital and having had the original surgery in a rural hospital (large or small) or at a Winnipeg teaching hospital placed one at elevated risk as compared to a nonteaching urban hospital. For those with multiple diagnoses (at time of the original surgery), there was a risk of 1.72 for readmission as compared to those whose only diagnosis was cholelithiasis. Complex surgery was not a risk factor for readmission as compared to simple cholecystectomy. After adjustment for all factors in Table 3, being a Native American placed one at 1.46 odds for readmission (95 per cent confidence interval = 1.17, 1.81).

Discussion

This study demonstrates that Native American women in Manitoba experienced a high rate of cholecystectomy. The age of operation was much earlier; they suffered from a high rate of postoperative readmissions; and the rate of this surgery has not declined much over time. Two explanations, not necessarily mutually exclusive, can be offered: Native women are at higher risk for developing gallbladder disease; Native Americans receive differential care within the health care system of Manitoba.

The high risk for gallbladder disease among North American Native Americans has been recognized for some time, particularly among tribes in the southwestern USA.[2,3,5,6,12,13,14] All Native groups studied had higher prevalence than the White population as exemplified by the Framingham Study,[15] with the Pima occupying the extreme high end of the spectrum, similar to their position with regard to diabetes.

A female excess is observed among both Natives and the rest of the population, although the female/male ratio is higher among the former. Cholecystectomy rates are not synonymous with prevalence of gallstones and may be affected by such factors as lack of agreement about indications for surgery.[16] However, virtually every study—whether autopsy, population-based, or of surgical rates—demonstrates a female/male ratio of at least 2:1.[17] Therefore the female excess in cholecystectomy rates likely reflects an excess in gallstone disease in Manitoba women. It can be speculated that the greater female excess and younger age of onset among Natives can be attributed to the higher prevalence of obesity and greater fertility among younger Native women. Both obesity and parity have been implicated as risk factors for gallbladder disease,[17–19] although the evidence is less consistent for Natives.[1–3,14,15] According to the 1981 Canada Census, an average of 4.8 children were born to ever-married Native women living on reserves, compared to 2.5 among others. Thirty-five per cent of Native women gave birth to six or more children, compared to only 8 per cent among non-Natives.[20] In terms of obesity, the Nutrition Canada Survey during the early 1970s indicated that Native women had higher mean weight than Canadians nationally at all age groups, whereas in men higher weights were observed only among those over the age of 50.[21]

Although the health care utilization pattern among Natives differs from that of the rest of the population, this is not sufficient to account for the higher surgical and readmission rate. The persistently high female rate is likely the result of a sustained disease burden unaffected by changing surgical practice in the province. The reason for the higher readmission rate is not known. Natives were as likely to receive bile duct exploration and the overall length of stay was also similar. Thus the differences were not likely due to retained stones at initial surgery.

Ethnic differences in post-cholecystectomy complications persist after controlling for various demographic and

TABLE 2—Percentage Readmitted to Hospital after Cholecystectomy by Time Period and Native Status

	1972–78			1979–84		
	Native American	All Others	Rate Ratio (95% CI)	Native American	All Others	Rate Ratio (95% CI)

medical care factors in a multivariate analysis. However, the types of "risk factor" information routinely available from health insurance claims data is limited. Differences in the distribution of lifestyle (smoking, diet, alcohol, physical activity), socioeconomic status, anthropometric and physiological indices (obesity, lipids, blood sugar, etc.), and parity may account for the observed "ethnic" differences and the continuing high rates.

Most studies of post-cholecystectomy complications tend to derive from one or more teaching hospitals or from one surgeon's experience.[22,23] These studies give complication rates reflecting only immediate postsurgical morbidity[24] and underestimate the true rate of adverse events which may occur after discharge from hospital.[8] Our study is population-based and includes all readmissions even if they occurred at different hospitals than the original surgical event. While not a definitive measure of complications of cholecystectomy, the use of readmissions data served to illustrate the differences between the Native experience and that of the rest of the population.

Two HRSA Programs Benefit the Homeless

• The Health Resources and Services Administration (HRSA) of the US Public Health Service recently announced an award of about $14 million by HRSA to 109 existing health care projects for the homeless in 43 states and the District of Columbia. These 1989 funds will supplement the second year of operation for the projects; $46 million was provided in the first year of operation.

The projects have provided health care to more than 236,000 homeless persons, including many family units with children. Approximately 60 percent of those served are minority group members. In 1989, the number of homeless persons served by the 109 projects is expected to total more than 450,000.

• The "doctors on wheels" project—a major effort to provide outreach health care for the homeless of New York City—is supported by HRSA under its health care for the homeless program. The mobile unit, which is equipped with supplies and a small waiting room, is staffed by health professionals and makes regular stops each week at facilities for the homeless in Manhattan. Sponsored by the New York Children's Health Project, the program is directed by Dr. Irwin Redlener, chief of ambulatory pediatrics at the hospital.

During the three-year fiscal period 1987–89, the project received nearly $1 million from HRSA. The project also operates a second van that serves the homeless in the Brooklyn and Queens sections of New York City. The first mobile unit was acquired with the assistance of singer Paul Simon.

For further information about these projects, contact Frank Sis at HRSA, USPHS, Department of Health and Human Services, 5600 Fishers Lane, Room 14-43, Rockville, MD 20857. Tel: (301) 443-3376 or -3377).

Excessive Burden of End-State Renal Disease among Canadian Indians: A National Survey

T. Kue Young, MD, MSc, Joseph M. Kaufert, PhD, John K. McKenzie, MD, Audrey Hawkins, BN, and John O'Neil, PhD

Abstract: Analysis of data from the Canadian National Renal Failure Register indicates that Canadian Natives are at much higher risk for end-stage renal disease (ESRD) than the Canadian population in general. Using two population estimates for the total Native population, the age-standardized incidence rate of newly registered ESRD cases between 1981 and 1986 among Natives was at least 2.5 times (and may be as high as four times) the national rate. Natives were particularly at higher risk for ESRD to diabetes, glomerulonephritis, and pyelonephritis, whereas for the other causes the risk was no different from that of other Canadians. As technologically sophisticated treatment facilities are only available in major urban centers, Native ESRD patients and their families living in remote areas of Canada are faced with major psychosocial disruptions of relocation. (*Am J Public Health* 1989; 79:756–758.)

Introduction

Ethnic differences in the incidence of end-stage renal disease (ESRD) have been observed in some populations. In the United States, Blacks and Hispanics generally have higher rates than Whites.[1–3] Recent reports from the American Southwest also show that the rate among some Indian tribes, particularly the Zuni, exceed those of Whites by several- fold.[4,5] It is not clear if such a phenomenon is also observed in other Amerindian groups across the continent.

This paper reports on the first phase of a multidisciplinary study examining the epidemiological, clinical, and sociocultural dimensions of ESRD among Canadian Indians.

Methods

The Canadian National Renal Failure Register—jointly funded by the Department of National Health and Welfare, Statistics Canada, and the Kidney Foundation of Canada—has collected statistics on chronic renal failure patients since 1981. The register aggregates demographic and clinical data from 75 treatment centers in the nine Canadian provinces with specialized dialysis and transplant programs. It is population-based, voluntary and covers all active renal treatment centers in the nation.[6] Data on all registered patients is updated yearly from medical record reviews in each center to reflect changes in treatment modalities and location, transplant experience and mortality. Patient profiles include age, sex, racial origin, birth date, course of treatment, method of treatment, transplant experience, donor type, cause of graft failure, and cause of death. There is no duplicate counting even as patients are transferred from one center to another. The coding categories and entry criteria are generally compatible with those developed and used internationally by the European Dialysis and Transplant Association.[7]

We requested special computer runs and obtained custom tabulations of all newly registered ESRD cases during the period 1981–86, comparing Native and non-Native patients. In the designation of "racial origin," the National Register distinguishes between Caucasian, Oriental, Black, Native, and other groups. Although the term "racial origin" connotes genetic differences, ascription of individuals to the above categories is more generally made on the basis of "ethnicity," a term which combines genetic (and usually physiognomous) characteristics with socio-cultural, environmental, political, and administrative attributes. The criteria for determining these attributes are subject to considerable interpretation and, at the present time, the National Register does not provide detailed criteria to the individual reporting renal units for establishing "ethnicity" or "racial origin."

To investigate how people of Native ancestry were designated, we interviewed the clinicians responsible for data entry and reviewed the records of one provincial unit. In the central dialysis unit with the highest proportion of Native clients, review of the register and preliminary audits of patient records of all clients (N = 63) revealed that 28 percent were designated as Native and 72 percent non-Native. We searched for documentation of band number (which signifies legal membership in a government recognized Indian group), home community address, indication of need for translation services in a Native language, staff notations indicating self-ascription of Native identity, or staff notes indicating attribution of Native ancestry on the basis of physical characteristics or personal history. None of the patients listed in the registry as non-Native were found to have any information indicating Native ancestry. All but four of the patients categorized as Native by the registry had official Indian band numbers listed; among these four individuals, records and follow-up interviews with the nursing staff indicated that two had described their identity as Metis or non-status Indian and two were identified on the basis of language patterns, home address, and physical appearance as being of Native ancestry.

In Canada, there are several categories of Native Peoples. These include Registered (Status or Treaty) Indians, non-status Indians, Metis, and Inuit (Eskimos). Metis are descendants of mixed Indian-White marriages during the early settlement of the Canadian West. They constitute a distinct cultural and political group in Canada today. According to the 1981 Census of Canada, Registered Indians constituted only 60 percent of all Native Peoples in the country. Since it is not clear as to the true denominator of the Native cases identified by the National Register, two different estimates of the Native population of Canada were used in the

computation of rates. The Department of Indian and Northern Affairs (DINA) publishes annually the population by age, sex, and residence of all Registered Indians in Canada. The 1984 (representing the mid-point of the study period) Registered Indian population serves as the "A" estimate. This is a low estimate and assumes all Native cases in the register were exclusively Registered Indians. A second, higher estimate of the denominator assumes that the Native ESRD cases belong to all categories of Native Peoples. By dividing the "A" population estimate by 60 percent we obtained an estimate (the "B" estimate) of the total Native population in 1984. It is likely that the true denominator lies somewhere between the "A" and "B" estimates.

As the age structure of the Native population differs substantially from the Canadian national population, the former being much younger, age standardization was performed using the Canadian population as standard. The mid-period population was obtained by averaging the 1981 and 1986 Census of Canada population by age-sex groups. In the comparison of total all-causes incidence rates, the direct method of age-standardization was used. In the comparison of cause-specific rates, standardized incidence ratios (SIR) were computed using the indirect method, due to the much smaller population within each age-sex class. Ninety-five percent confidence intervals were computed for all rates and ratios.[8]

Results

During the period 1981–86, there were a total of 8,432 newly registered cases of ESRD in Canada (5130M, 3302F), of whom 304 were categorized as Native (162M, 142F). Table 1 indicates that at all age-sex groups, the Native rate (23.1/100,000 using the "A" estimate and 13.9/100,000 with the "B" estimate), regardless of whether the "low" or "high" population estimate was used, was higher than the Canadian national rate. Age-standardization resulted in an even higher Native rate, which may be as high as four times and at least 2.5 times the national rate.

The proportion of cases due to diabetes and glomerulonephritis is higher among Natives than all Canadians, whereas the proportion due to renovascular disease and polycystic kidneys is lower (Table 2). In terms of the SIR by cause, Natives are at least at twice the risk as all Canadians for ESRD due to diabetes, glomerulonephritis, and pyelonephritis. Sixty-two percent of Native patients received hemodialysis as the initial treatment compared to 56 percent among all Canadians.

The crude prevalence of ESRD at period end (December 31, 1986) was 22.3/100,000 for all Canadians, and 53.4 ("A" estimate) or 32.0 ("B" estimate) for Natives. The cumulative mortality rate for all newly registered patients during this period was comparable for the two groups: 33.1 percent for all Canadians and 31.9 percent for Natives.

Discussion

This national survey confirms clinical observations and limited mortality and hospital utilization data that a higher burden of ESRD exists among the Native population of Canada. The extent and magnitude of ESRD in the Indian population of Canada has not been adequately assessed. However, several crude estimates based on death certificates and medical care insurance claims suggest that the risk of renal disease is higher among Indians than the general population.

A study of mortality among residents of Indian reserves aged 1–69 in seven provinces from 1977–82 showed that, while kidney diseases were not among the 10 highest ranking causes of death, Indian men had two times and Indian women four times the risk of dying from kidney diseases compared to Canadians nationally.[9] According to claims submitted to the Manitoba Health Services Commission, the provincial health care insurance agency, the hospital separation rate for Manitoba Indians for all genitourinary diseases (ICD-9 codes 580–629) was 15.5/1000 per year, compared to 10.2/1000 for all Manitobans. For the rubrics "nephritis, nephrotic syndrome and nephrosis" (codes 580–589) the Indian rate was 1.4/1000 and the provincial rate was 0.4/1000. The age-standardized ratio for all genitourinary diseases comparing Indian with the provincial total was 2.3.

TABLE 1—Incidence Rate of Newly Registered Chronic Renal Failure: Comparison of Natives with all Canadians, 1981–86

Age-Sex Group	All Canadians	Rate Ratio Native:Canada (A)	95% CI	(B)	95% CI
Male (years)					
0–4	0.71	1.90	0.46, 7.94	1.14	0.28, 4.76
5–14	0.68	3.31	1.45, 7.62	1.99	0.87, 4.57

Polycystic Kidneys	7.2	2.6	1.5	0.7, 3.0	0.9	0.4, 1.8
Drug-Induced Nephropathy	1.8	0.3	0.8	0.0, 4.4	0.5	0.0, 2.8
Others	14.4	14.5	3.3	2.4, 4.4	2.0	1.5, 2.7
Unknown	10.9	12.5	5.3	3.8, 7.2	3.3	2.3, 4.4

NOTE: (A), (B)—See text for definition of different Native Canadian population estimates. SIR = Standardized Incidence Ratios.

The precise causes for this phenomenon are not known but may have been due to the higher prevalence of diabetes mellitus[10,11] known to be present in many Indian groups. Diabetes accounts proportionately for more ESRD cases among Natives than other Canadians. The incidence of impetigo-related post-streptococcal glomerulonephritis is also higher in Native communities, although it has yet to be established that such cases are more likely to proceed to ESRD. It is also interesting that, among the different sites of cancers, Indians are particularly at high risk for kidney cancers.[12,13] It would therefore appear that, for a variety of environmental and genetic reasons, the kidneys of Canadian Natives are highly susceptible to pathologic derangements which may result in ESRD or malignant change.

The lack of uniform and clearly defined criteria for racial origin in the National Register and its confusion with ethnic identity, however, impose some reservation on our conclusions. Many people designated as Native using nongenetic criteria are usually of mixed racial heritage which obviously complicates discussions of genetic predisposition to certain diseases. Furthermore, different renal reporting centers may have greater or lesser sensitivity to sociocultural or environmental criteria for determining Nativeness which may contribute to either over- or under-reporting errors. To assess variability in the designation of ethnicity, current criteria and validity of data on Native ancestry in each of the country's treatment centers need to be documented.

The demonstration of an excess in the burden of ESRD among Canadian Natives has profound implications for health care delivery. In order to survive, patients must depend on technologically sophisticated and professionally controlled treatment provided in urban hospitals. Many Native communities in Canada are located in remote areas, and relocation of Native patients and their family members for medical treatment disrupts social support patterns and creates a host of psychosocial problems.

Further epidemiological analyses will determine ethnic differences in the distribution of risk factors, types, and frequency of complications, survival experience, the impact of urban migration and interaction with medical technology. Concurrently the cultural and socioeconomic basis for discontinuities between service providers' and Native clients' interpretation of treatment alternatives, risk factors, and quality of life will be examined.

Utilization of Hospital Services by Cardiovascular Patients, Alberta, Canada

KYUNG S. BAY, PHD, MARGARET MAHER, MHSA, AND SIMON J. K. LEE, MD

Abstract: Using hospital discharge records, and United States DRG (diagnosis related groups) data, we studied hospital utilization by cardiovascular patients, associated hospital expenditures, and the per capita cost of treating cardiovascular diseases in Alberta, Canada between 1971 and 1986. Expressed in constant 1984 Canadian dollars, the estimated total hospital cost increased from $84 million in 1971 to $131 million in 1986; during this period the Province of Alberta spent about $51 Canadian per resident each year for cardiovascular hospital services. It was noted that rural residents consumed a higher volume of resources per capita than their urban counterparts. A patient origin-destination analysis indicated an increasing dependence of rural patients on urban hospitals for secondary or tertiary care, underscoring the effects of medical technology on referral patterns. (*Am J Public Health* 1989; 79:759–764.)

Introduction

Cardiovascular (CV) disorders are the leading contributor to time spent by Canadians in acute care hospitals. This has been a major concern to hospital planners because of the growing emphasis on health care cost containment. Both the total and per capita costs of CV disorders are difficult to estimate because Canadian hospitals are funded under global budget arrangements, and individual patient accounts are not generally maintained.

In most Western industrialized countries, the advent of a plethora of sophisticated techniques and instruments for treating CV disorders over the past two decades has changed the nature of their hospital care. These changes have been accompanied by declines in CV disease incidence rates. Although advanced technology has been associated with higher health care costs, the impact of technological changes cannot be assessed without proper cost estimates. Moreover, the health care cost saving due to the recent emphasis on life-style modification cannot be substantiated without reliable estimates of the total costs involved.

Canadian mortality rates attributed to ischemic heart disease increased until the 1960s and then declined approximately 1.7 per cent for males and 2.4 per cent for females annually during the 1970s;[1] age-adjusted mortality rates for ischemic heart disease declined by 16.4 per cent between 1969 and 1977,[2] as compared to a 20.7 per cent decrease in the US.[3] It is generally conceded that this decline is real rather than an artifact of diagnostic variations, increased awareness, or changes in disease classification. Specific causes of declining mortality rates have been predominately related to changes in CV risk factors and, secondarily, to improvements in and accessibility of coronary medical services.[1,3]

In Canada, approximately 8.5 per cent of the gross national product is devoted to health care.[4] Capital and operating hospital expenditures are normally provided by the provincial governments and individual patients are not billed directly. Physicians and surgeons who practice in hospitals bill the provincial health care insurance plans directly on a fee-for-service basis, virtually eliminating financial barriers to health services. Removal of financial deterrents to seeking health services, however, has resulted in increased hospital and medical care utilization and associated expenditures.

Alberta, one of 10 Canadian provinces, has a population of 2.4 million. Serving this population are 123 general acute care hospitals providing an average of 5.5 beds per 1,000 persons. On an average annual basis, Albertans are admitted to hospital 0.19 times and spend 1.4 days in hospital. The total health care per capita cost in 1984 was about C$1,721, and the government allocated approximately C$698 per capita for Alberta hospitals.[5] During the study period (1971–86), all hospitals in Alberta subscribed to the Professional Activity Study (PAS) hospital discharge abstract system, generating about 400,000 separation records per year. The files are fully computerized and available for research and planning purposes.

Using hospital discharge data, Newman[6] reported that CV disease ranked as the fourth and sixth most important cause of hospitalization for Alberta males and females, respectively, in 1980, but was the outstanding cause of time spent in Alberta acute care hospitals. This high volume of acute care hospitalization has rendered CV disease a major health care expenditure.

The purpose of this study was to explore utilization and resource consumption by CV patients in acute care hospitals in the Canadian province of Alberta. Specific objectives were:

- An examination of global patterns and trends in acute care hospital utilization from 1971 and 1986;
- An historical comparison of total, per capita, and per discharge hospital costs;
- A comparison of utilization rates over time among geographic regions of Alberta; and
- An exploration of the care-seeking patterns of patients.

Methods

Data Source

The primary source of the clinical data was PAS records, a patient discharge abstract system developed for acute care hospitals by the Commission on Professional and Hospital Activities, Ann Arbor, Michigan. Variables coded on the discharge abstract include age, sex, date of admission and discharge, length of stay, primary, secondary and tertiary diagnoses, operation codes, discharge status, patient's home address and other pertinent variables. The current disease coding scheme used for diagnoses and operation codes is the

ICD-9-CM; diagnosis related group (DRG) codes are available only for separations generated in 1984 and thereafter.

The CV disease diagnoses were organized according to the Major Disease Category of the revised ICD-9-CM version of the DRG classification system.[7] Abstract files were extracted for all Alberta residents discharged from acute care hospitals with CV disorders between 1971 and 1986; DRG codes were assigned retrospectively for the discharges generated before 1984. During the course of this retrospective assignment of DRG codes for pre-1984 discharges, it became apparent that differences in coding schemes precluded the achievement of perfectly comparable DRGs. After the revised ICD-9-CM circulatory DRGs were finally adjusted, we constructed similar DRG groups for the years 1971 to 1978 inclusive, incorporating the H-ICDA coding scheme for 1971 to 1973 and the H-ICDA-2 coding scheme for 1974 to 1978. Initial cross-tabulations and comparisons with the Canadian Diagnostic Listing system indicated that the resulting DRG groups were relatively similar and representative of overall CV disorders (The extensive Coding Guides used for this project are available from the authors on request). Since this study was designed to study general patterns and trends of CV utilization and did not involve epidemiological assessment of individual disease categories, we believe that this limitation does not imply any significant compromise in the findings and conclusions.

We examined the use of hospital resources incorporating as proxies the DRG weight values used by the US government, henceforth referred to as the weighted DRG (See Appendix I). One unit of the DRG weight is equivalent to the resources required by an average American hospitalization episode. The weighted sum of discharges provided a measure of relative resource consumption by a particular group of hospital patients. The US Prospective Payment Assessment Commission[8] provided the DRG weights in effect during the fiscal year 1987 and average charges and geometric mean lengths of stay based on 1984 data.

The other major data source was the census data released by Statistics Canada for the years 1971, 1976, 1981, 1986, and estimates of the Alberta population for the intercensus years. The Alberta government's report on hospital expenditures for the year 1984 was also used.

Analyses

Total number of discharges, total number of patient-days, and total weighted DRGs were compiled for each year from 1971 to 1986 for medical, surgical, and combined CV DRGs. By using the average hospital cost per unit of the weighted DRG, experienced in 1984 by all Alberta hospitals for all discharges (CV and non-CV), a particular group's weight values were converted into CV hospital service cost estimates in 1984 constant Canadian dollars. By dividing these basic measures by the corresponding population figures, population-based hospital utilization rates were derived including the number of discharges per 1000 person-years, the number of patient-days per 1000 person-years, and the cost per person-year in 1984 Canadian dollars. By dividing the total patient-days, weighted DRGs and costs by the corresponding total number of discharges, per-case measures such as average length of stay and average weighted DRG per discharge were also derived. Alberta was divided into metropolitan, suburban, and rural areas and annual per capita and per case utilization rates were computed and compared for the three regions.

The final step of the analysis centered on an investigation of the care-seeking behaviors of patients with CV disorders. Instead of using the traditional discharge and patient-day indicators as measures of resource use, the weighted DRG was used for a more direct assessment of resource consumption and allocation patterns. Relevance indices[9,10] measure the extent to which CV patients of a geographic area were dependent on the resources of a hospital group; commitment indices[9,10] measure the extent to which selected hospital(s) allocated CV resources to patients originating from a particular geographic area (see Appendix II for definitions of these indices). The indices were obtained for each study year and historical patterns were identified.

Results

Hospital Utilization: All DRGs

If the average sum per DRG weight unit in 1984 paid by the US government (US$4,155) is valid for Alberta cases, this value may be applied to the Alberta weighted DRG. As total Alberta weighted DRGs increased from 25,300 in 1971 to 39,400 in 1986, the corresponding cost estimates would be US$105 million and US$164 million, respectively, for 1971 and 1986, and the total cost estimate over the years would be US$2.07 billion. These amounts would have been paid to hospitals for CV services if the Alberta hospital system had adopted the US DRG prospective payment system during the study period. However, the validity of this approach can be seriously challenged as Alberta hospitals operate very differently from their US counterparts and the data of this study included the whole population while the US data were based primarily on those aged 65 or over (all Medicare and a small portion of Medicaid discharges). Thus, as noted previously, a somewhat different approach was adopted to address the above concerns.

Cost per DRG Weight Unit

During 1984, Alberta acute care hospitals generated 439.6 thousand discharges yielding a total of 337.5 thousand weighted DRG units. Thus the average weighted DRG value per discharge for all Alberta discharges (both CV and non-CV cases) was 0.77 units, much lower than the theoretical value of 1.0. In order to compare the average weighted DRG between the US and Alberta, selection criteria were applied to the two data sets. For US data, only those DRG codes which were applicable to persons over age 65 were selected; for Alberta data, patients under age 65 were excluded, thus making the two data sets composed of groups 65 years and over. The average weight values per discharge for the elderly were 1.11 and 1.03 for the US and Alberta, respectively. The lower Alberta figure suggests that Alberta hospitals experienced relatively less resource-intensive case-mixes in 1984. It is interesting to note that DRG127 (Heart failure and shock) ranked the highest of total weighted DRGs for the elderly group in both US and Alberta; this particular DRG accounted for 4.3 per cent and 3.9 per cent of the total elderly weighted DRGs in 1984 (Alberta data are available from the authors on request). During 1984, Alberta hospitals spent about C$1,121 million to operate 123 acute care hospitals resulting in C$3,321 per unit of weighted DRG.

Hospital Utilization: CV DRGs

Historical trends associated with hospital utilization by CV DRGs (DRG Codes 103–145, see Appendix I for listing) are presented in Table 1 for per capita rates and in Table 2 for per case rates. During the 16-year period, the Alberta

Patient-days per 1000 person-year
†Cost per person-year in 1984 Canadian $

population increased by 44.3 per cent, but the number of discharges increased by only 29.6 per cent, indicating an overall decline of hospital admission rates and/or a decline of CV incidence. The per capita discharge rate declined 10.6 per cent from 14.1 per 1,000 person-years in 1971 to 12.6 in 1986. The total number of patient-days declined 8.6 per cent and the per capita rate decreased as much as 36.0 per cent. As these measures do not take into account case-mix variation, these statistics do not reflect necessarily the resource consumption by CV patients. Although it is not perfect, the resource consumption estimate based on DRG classification provided a more accurate picture.

Using the average cost per weighted DRG unit in 1984 (C$3,321), the total estimated cost increased from C$84 million in 1971 to C$131 million in 1986, a gain of 56.0 per cent which is slightly greater than the population growth (44.3 per cent); the per capita cost for CV hospital services increased minimally from C$52 to C$55. Thus it appears that decreased CV morbidity, supported by declines of discharge and mortality rates, did not result in a significant reduction of the per capita cost; per capita cost was more highly associated with health care system variables than with epidemiological variables. There had been a gradual decline in the per capita cost for the years 1976–81, corresponding to the time period when Alberta experienced economic growth. With the recession and stabilization of the population since 1982, the per capita rates gradually increased to the 1972 level where the highest rates were observed, suggesting the effects of health service supply on utilization.

*Patient-days per discharge
#Weighted DRG per discharge

For per case rates (Table 2), the average length of stay declined 29.7 per cent, from 13.8 days per discharge in 1971 to 9.7 days in 1986; however, the average weighted DRG values gradually increased from 1.10 to 1.32 (+20.0 per cent), suggesting a substantial shift of case mix toward more resource-intensive admissions over the years. Thus, the overall decline of per capita discharge and patient-day rates coincided with a shorter average length of stay and increased case mix complexity; however, these factors had a mutually canceling effect resulting in a relatively stable per capita cost.

Medical DRGs

For medical DRGs (DRG Codes 121–145, see Appendix I for listing), the discharge rate declined 12.2 per cent while the patient-day rates experienced a remarkable decline of 43.0 per cent. Overall, the per capita cost for medical discharges declined about 8.8 per cent. The decline in the patient-day rate suggests an overall productivity gain in medical DRGs. This observation is also supported by the per case rates as shown in Table 2. During the 16-year period, the case mix complexity, as measured by average weighted DRG per discharge, increased slightly (4.4 per cent) while the average length of stay declined 35.0 per cent, suggesting that Alberta hospitals were admitting patients with greater case mix complexity but keeping them a shorter length of time on average.

Surgical DRGs

For surgical DRGs (DRG codes 103–120, see Appendix I for listing), per capita discharge rates declined from 2.6 per 1,000 person-years in 1971 to 2.1 in 1981 but increased to 2.5 in 1986 (Table 1). The patient-day rates exhibited a similar pattern but declined slightly (−10.8 per cent). In sharp contrast to these rates and the medical DRG per capita cost, the overall per capita surgical cost increased 41.2 per cent, reflecting the more resource-intensive case mixes in later years. During the 16-year period, surgical CV cases gradually became more resource-intensive suggesting the effects of a general shift to higher technology and greater sophistication of surgical methods. The portion of all CV per capita cost attributable to surgical DRGs increased from 32.7 per cent in 1971 to 43.6 per cent in 1986, suggesting a substitution effect of medical DRGs by the surgical DRGs. The case mix complexity of surgical DRGs increased dramatically during the period: the average weighted DRG value increased from 1.97 to 2.89, an increase of 46.7 per cent. Alberta hospitals, however, were able to reduce the average hospital stay about one day (from 14.2 to 13.3), indicating the effects of medical technology and tighter bed supply.

Geographic Factors

The results of a regional comparison are summarized in Table 3 for all CV DRGs. Rural discharge rates for all CV DRGs were about twice those of the metropolitan areas,

whereas suburban rates were slightly higher than metropolitan rates. Rural discharge rates changed very little over the years while metropolitan residents experienced a slight decline. Throughout the study period, rural residents used hospital beds 52-83 per cent more than their metropolitan counterparts on a per capita basis, resulting in higher per capita CV costs for rural residents. Thus it is clear that rural residents of Alberta were consuming a much higher volume of hospital resources over the study years. This is consistent with findings of other utilization studies conducted in Alberta;[11,12] obviously these differences cannot be explained by the medical need model. It appears that the most probable factors accounting for these differences are associated with system-related determinants of utilization such as multiple admissions for the same disease episode for rural residents through referral networks; higher bed availability in rural communities;[10] more cautious practice by the physicians for patients originating from rural areas; and lack of alternative services in rural areas. To substantiate this interpretation, utilization rates for surgical DRGs were tabulated separately (see Table 4). As expected, there were very few discernible systematic variations in per capita utilization rates among the three geographic areas in Alberta. Thus it may be concluded that the rural-urban variation is mostly due to system-related determinants of health service utilization.

Patient Flow Patterns

The results of the patient origin-destination analysis are summarized in Table 5. The indices were derived using total weighted DRGs attributable to each segment of patient origin and destination combination, partially controlling the variation in resource needs due to case mix differences. From a community perspective, results indicated a markedly increasing tendency for those in rural areas in Alberta to depend on metropolitan hospital resources. For example, the relevance index of metropolitan hospitals to the rural area, RI(M,R), or the dependence of rural residents on metropolitan hospitals, increased from 26.3 per cent in 1971 to 46.8 per cent in 1986; almost one-half of the weighted DRGs generated by rural residents represented resources consumed in metropolitan hospitals in 1986. Conversely, the relevance index of rural hospitals to rural areas, RI(R,R), declined from 71.8 per cent to 48.1 per cent. Some of this shift may be attributed to technological changes as highly sophisticated facilities and interventions by specialists are available only in urban large hospitals. The relevance index of metropolitan hospitals to suburban area, RI(M,S), also increased from 19.9% to 31.5%. Thus it is obvious that both rural and suburban areas of Alberta are increasingly depending on metropolitan hospital CV services.

From a provider perspective, commitment indices revealed an inverse relation between the level of care available within a hospital group and the commitment of that group to

patients within their respective communities. Between 1971 and 1986, metropolitan and suburban hospitals devoted decreasing amounts of CV resources to their respective residents and, concurrently, significantly increased their allocation of CV resources to rural patients. Metropolitan hospitals allocated 75.7 per cent of their resources to metropolitan residents in 1971, but the proportion decreased to 63.3 per cent in 1986. The commitment index of metropolitan hospitals to rural hospitals, CI(M,R), increased from 21.3 per cent in 1971 to 31.4 per cent in 1986. Similar trends were observed for suburban hospitals.

Selected DRGs

Cost estimates for relatively common medical and surgical DRGs are presented in Table 6 suggesting disease specific trends. As fixed costs are assigned to each of the DRG categories, the trends are identical with the number of admissions in each category. For example, DRG122 (Circulatory Disorders with Acute Myocardial Infarction without complications, alive) and DRG127 (Heart failure and shock) increased 56.2 per cent and 48.9 per cent, respectively, slightly more than the rate of population increase (44.3 per cent) whereas DRG130 (Peripheral vascular disorders, 70+ and/or Complication or Comorbidity) increased only 31.6 per cent. The number of coronary bypass procedures (DRG106–7) in 1986 was 5.6 times that of the 1971 value, while valve procedures (DRG104–5) more than doubled, indicating the major causes of the surgical DRG cost increase. DRG108–12 (Cardiothoracic and vascular procedures) almost tripled, while DRG119 (Vein ligation and stripping) declined 41.4 per cent. For the 16-year period, the largest portion of total CV costs was attributed to DRG108–12 (17.8 per cent), DRG127 (10.8 per cent), and DRG122 (9.0 per cent). It is estimated that valve and bypass procedures combined cost Alberta taxpayers in 1986 about C$15 million for hospital services alone. It should be recognized that these figures do not include other costs associated with CV disorders such as physician and out-of-hospital services.

DRG106-7 Coronary bypass procedures
DRG108-12 Cardiothoracic and vascular procedures
DRG119 Vein ligation and stripping

On the basis of these findings, we draw the following conclusions:

- The overall downward trends in per capita CV utilization in Alberta were consistent with the overall decreasing Canadian hospital utilization rates and decreasing CV morbidity and mortality in developed countries; however, this decline did not contribute to a decrease in the per capita hospital cost which remained relatively stable at about C$51. The introduction or increased use of more resource intensive surgical technology appears to have offset cost savings due to declining utilization rates;
- High per capita hospital utilization rates were primarily a rural phenomenon for medical DRGs, reflecting the effects of the availability of more beds in rural areas, technological changes, referrals, more cautious medical practice patterns by physicians for rural patients, and perhaps the effect of tighter bed control implemented by the provincial government during the latter part of the study period; however, no discernible variation in utilization rates was found for surgical DRGs;
- A substitution effect of the medical DRGs by the surgical DRGs occurred during the study period which significantly influenced the utilization of CV resources in view of the high costs associated with the major surgical DRGs;
- The increasing dependency of non-metropolitan patients on metropolitan hospitals' CV resources, combined with the increased use of metropolitan hospital resources by the elderly identified in other studies,[11] could partially account for the perceived bed shortage and long waiting lists for elective surgery experienced by metropolitan residents during the latter part of the study period. This would suggest a need for shifting resources to urban hospitals;
- This analysis provides some baseline information with which to measure the impact of health promotion programs especially if Canadian provinces adopt a DRG-based reimbursement scheme for financing and managing hospital services.

APPENDIX II

The Definitions of Relevance and Commitment Indices

The following formulae were used for the computation of relevance (RI) and commitment (CI) indices. This is a modification of common formulae found in the literature:[9,10] the number of admissions or patient days used as a utilization measure was replaced by the weighted DRG values.

$$RI(H,A) = WDRG(H,A)/WDRG(A)$$

$$CI(H,A) = WDRG(H,A)/WDRG(H)$$

where H denotes one or a group of hospital(s);
A a geographical area;
WDRG(H,A) total weighted DRG values generated at a hospital(s) H by the residents of a geographic area A;
WDRG(A) total weighted DRG values generated at all hospitals by the residents of an area A;
WDRG(H) total weighted DRG values generated at a hospital H by the residents of all areas.

The relevance index may be interpreted as the dependence of an area A on a particular hospital H for health services in terms of resource needs, or the market share of area A by the hospital H. The commitment index may be interpreted as a commitment or allocation of resources by a hospital H to serve an area A.

The Association of Age-Related Macular Degeneration and Lens Opacities in the Aged

INGRID Y. LIU, MD, MPH, LON WHITE, MD, MPH, AND ANDREA Z. LACROIX, PHD

Abstract: Data from 3,087 persons age 45 or older in the National Health and Nutrition Survey, 1971–74, showed that subjects with lens opacifying disease had an increased odds for age-related macular degeneraton (AMD) compared to those who had no lens opacities. The crude odds ratio for aphakic patients was 4.6 (95% CI = 2.5, 8.6). The association remained after controlling for age, sex, and systolic blood pressure (a common risk factor) in a logistic regression model. These data are consistent with the hypothesis that light-induced damage may contribute to both lens and retinal disease and suggest that cataract extraction without implantation of ultra-violet/blue light absorbing intraocular lens may place subjects at increased risk of AMD. (*Am J Public Health* 1989; 79:765–769.)

Introduction

Age-related macular degeneration (AMD) and cataracts are two of the most common causes of visual impairment in older persons. Differing sampling methods and diagnostic criteria make prevalence estimates difficult, but the World Health Organization estimated in 1982 that 17 million persons in the world were blind as a result of cataracts. Ferris notes that AMD was the leading cause of registered blindness in the United States and Great Britain as early as 20 years ago.[1] While each disease affects a separate structural component of the eye, their dramatic increase in prevalence with aging suggests common or related processes may be responsible for both conditions.

Although the pathogenesis of neither condition is well understood, mechanisms that involve light-mediated damage have been theorized for both.[2–4] According to these theories, damage to the lens and/or retina occurs when the body's defenses, such as antioxidant stores and enzyme systems, fail or are overwhelmed. Light has been shown to induce retinal lesions in many mammals.[5–7] A role for free-radical-mediated damage in the development of cataracts is supported by the finding of deficient superoxide dismutase activity in cataractous human lenses.[8]

Since light must pass through the lens to reach the retina, cataracts may actually retard the development of AMD. The yellow pigmentation that characterizes nuclear cataracts may filter out blue light that is felt to be especially damaging.[9] Zigman and Collier noted in the diurnal gray squirrel that the yellow pigmented lens filtered near-ultraviolet (UV) radiant energy and protected the retina from physical and functional damage.[5]

There have been very few population-based studies examining this theory. Sperduto, *et al*, found no association between cataracts and AMD in the Framingham Study when the various age-related lens changes were pooled.[10] On reexamination of the same data, when specific types of cataracts were studied, they found a positive association between AMD and cortical changes and a negative association with nuclear sclerosis.[11]

An interesting and important corollary, if some lens opacification is protective of the macula, is that an increased risk may be imposed by surgical removal of cataractous lens. The Report of the Cataract Panel in Vision Research—A National Plan: 1983–87 suggests that aphakic eyes may be at special risk for retinopathy and maculopathy.[12]

From the Epidemiology, Demography, and Biometry Program, National Institute on Aging. Address reprint requests to Ingrid Y. Liu, MD, MPH, EDBP, National Institute on Aging, Room 618, Federal Building, 7550 Wisconsin Avenue, Bethesda, MD 20892. This paper, submitted to the Journal August 5, 1988, was revised and accepted for publication December 28, 1988.

The current study uses data from the first National Health and Nutrition Examination Survey (NHANES-I) to examine whether there is an association between the occurrence of AMD and lenticular opacities and whether aphakics compose a special risk group for AMD.

Methods

NHANES-I was a cross-sectional study of a probability sample (and partial oversample) of the civilian noninstitutionalized coterminus US population, designed to assess the prevalence of certain conditions. Details of the design and conduct of the survey are available elsewhere.[13] The visual component included a short ocular history and detailed examination for visual acuity, motility, and pathology, including tonometry and dilatation. Right and left eyes were examined and rated separately.

For this study, subjects having "senile macular degeneration," "senile disciform macular degeneration," or "senile circinate macular degeneration" were classified as having AMD, while all other persons served as controls (Table 1). A diagnosis of macular degeneration required pathological findings of "loss of macular reflex, pigment dispersion and clumping, and drusen"[14] as well as visual acuity of 20/25 or worse (best corrected) that was felt by the examiner to be due to the disease.

Lens conditions were grouped into four mutually exclusive groups—aphakic eyes, eyes with cataract and associated visual impairment, eyes with lens opacities but no visual impairment, and eyes with no lens opacifying disease (reference group). The cataract group was formed from all immature, intumescent, mature, hypermature, and morgagnian cataracts which the examiner felt were responsible for vision loss to the level of 20/25 or more (best corrected). The definitions for macular degeneration, cataracts, and aphakia are all consistent with those used by Klein in previous analyses of this data.[15]

The study population was restricted to subjects 45 years of age or older. The odds of having AMD for each of the lens opacifying conditions was calculated for right eyes and left eyes independently, as well as for persons with the condition in either eye. The reference group for the latter "person-measure" analysis was defined as those individuals with normal lenses bilaterally.

The relation of AMD with cataract was also examined for cataract subgroups based upon type of cataract. To be classified in either the "nuclear sclerosis" or "cortical cataract" subgroups, eyes were required to have cataracts identified in either the nuclear region or cortical region exclusively (as determined by a precoded variable in the data

TABLE 1—Frequencies of Persons with AMD and other Retinal Conditions by Lens Conditions, National Health and Nutrition Examination Survey, 1971–74

OS = oculus sinister (left eye)

set). All other cataracts were placed in a category designated as "other" which included eyes with mixed nuclear and cortical cataracts.

Crude weighted and unweighted odds ratios were initially calculated for all age groups combined and then after stratification by 10-year age groups. The results for weighted and unweighted analyses were not appreciably different. Unweighted odds ratios based upon actual frequencies with confidence limits calculated using Woolf's method[16] are presented in the tables. Finally the relationship of AMD with lens opacities was examined using a logistic model controlling for age, sex, and a common suspected risk factor for both: systolic hypertension.[15] The model was run using both unweighted data and a supplementary logistic regression program in SAS designed to incorporate sampling weights and take the complex sample design into account.[17] Results were similar and presented for both weighted and unweighted data.

Results

The study population included 3,738 persons (6,174 eyes) (Table 1). The prevalence of both lens opacifying disease and AMD increased dramatically with age (Figure 1). Lens disease was generally bilateral. AMD was found in 185 persons (316 retinas). In 131 (70.8 per cent) subjects the disease was bilateral.

In the univariate analysis, persons with cataracts were substantially more likely to have AMD than were persons with no lens abnormalities (Table 2). Similarly, persons with lens opacities but no visual impairment had an odds ratio of 2.5 (95% CI = 1.8, 3.5) when compared with persons with no lens opacities. A person with at least one aphakic eye had an even higher odds ratio for AMD (OR = 4.6; 95% CI = 2.5, 8.6).

Estimates of odds ratios measuring the strength of association between AMD and three categories of lens abnormality (opacities without visual impairment, cataracts, aphakics) are presented for three age strata in Table 3. All estimates remain greater than 1.0, with lower bounds of the 95 per cent confidence limits excluding 1.0 in the highest age stratum (where most of the cases were found) for the opacity without visual impairment and aphakic groups. The data shown in Table 3 are for individuals, with a person defined as having the condition if it was observed in either eye. Similar results were observed when analyses were conducted for the left and right eyes separately. These estimates suggest that

TABLE 2—Crude Odds Ratios and 95% Confidence Intervals ( ) for Association of AMD and Various Lens Opacifying Conditions in the National Health and Nutrition Examination Survey, 1971–74

	OD	OS	Either eye
No Lens Opacity	1.0	1.0	1.0
Lens Opacity without Visual Impairment	2.8 (2.0, 4.1)	2.7 (1.9, 3.8)	2.5 (1.8, 3.5)
Cataract	3.1 (2.0, 4.7)	2.0 (1.3, 3.2)	2.4 (1.6, 3.7)
Nuclear Sclerosis	2.5 (1.6, 4.1)	2.4 (1.5, 3.8)	2.2 (1.4, 3.5)
Cortical Cataract	2.8 (1.8, 4.4)	2.3 (1.5, 3.6)	2.4 (1.6, 3.6)
Other Cataract	3.7 (2.3, 6.1)	2.5 (1.4, 4.2)	2.9 (1.9, 4.7)
Aphakia	4.2 (1.8, 9.5)	3.5 (1.4, 8.4)	4.6 (2.5, 8.6)

OD = Oculus dexter (right eye)
OS = Oculus sinister (left eye)

the odds for having AMD may be increased 50 percent among persons with cataracts, 80 percent among persons with non-visually impairing opacities, and 200 percent among aphakic persons.

Multiple logistic regression analyses were conducted to appraise the association between lens abnormalities and AMD while simultaneously taking into account other major predictors of macular degeneration. The effects of each of the three primary categories of lens disease were simultaneously tested in a model containing age, sex, and systolic blood pressure. As shown in Table 4, odds ratios determined by this approach were similar to those described above with age stratification. Again, the strongest effect was associated with aphakia which had a weighted odds ratio of 2.0, followed by non-visually impairing lens opacities with a weighted odds ratio of 1.8. These results suggest that the increment in odds ratio associated with aphakia (as an example) is similar to that associated with 10 years of additional age.

The number of persons with exclusively nuclear or

95% CI in parentheses.

cortical cataracts was small in this study, making detailed stratified analysis impossible. However, the crude odds ratios relating AMD to both cataract subtypes were strong and statistically significant. Neither the strength nor direction of the relationships differed, as has been suggested in other studies.[11]

Discussion

The analyses presented here suggest an association between two age-dependent eye abnormalities: age-related macular degeneration, and opacifying lens disease. The finding suggests that the pathogeneses of these two conditions may involve a common etiologic (exposure) factor, a common susceptibility element, and/or common disease-modulating risk factors. Since the pathogenesis of neither condition is well understood, we can only speculate about the nature of the common factor(s).

Development of lens and retinal diseases might reflect the independent or combined effects of such factors as: excessive light exposure, especially over a period of years; an inefficient constitutional anti-oxidant system such as the enzyme superoxide dismutase (SOD); the influence of deficient dietary antioxidants such as vitamins A, E, or C; and/or the damaging effects of oxidation-potentiating factors such as dietary psoralens or certain drugs.[18] These concepts suggest that some patients with concurrent lens and retinal disease might reasonably be viewed as suffering from accelerating aging, a formulation in line with prior speculations that cataracts may be a marker for advanced physiologic age.[19]

In the logistic regression, the presence of cataracts was weakly associated with AMD (OR = 1.1, p = 0.4), possibly reflecting the difficulty of visualizing maculas in eyes with dense cataracts, even with dilatation. It is appealing to theorize that the weak association between cataracts and AMD in this study may be due to the fact that cataracts retard the transmission of light to the retina, decreasing the extent of light damage. Unfortunately, limitations of the data regarding the severity of either AMD or cataracts preclude investigating this possibility more completely. An alternative explanation of the weak relation involves the possibility that different kinds of cataracts may have differing pathogeneses. For some types, no common factors may be shared with macular degeneration.

The very strong association of AMD with aphakia suggests that a sudden increase in light transmittance after cataract removal may reinitiate and dramatically accelerate the progression toward frank macular degeneration. This speculation provides additional reason to support the trend toward routine implantation of intraocular lens following cataract extraction, particularly with a lens capable of reducing the transmittance of ultraviolet or blue light. Alternatively, it has been suggested that cataract extraction can produce retinal changes resembling AMD.* It has also been suggested that exposure to bright surgical lights at the time of cataract extraction may be responsible for damage to the macula.[20] Serial examinations comparing patients with intraocular lens implants and those without lens implants would help resolve this question.

By defining all retinas without frank AMD as controls, there is a high probability of misclassifying retinas with subclinical AMD in the control group. The conservative nature of this approach enhances the believability of the association of AMD and lens opacifying disease which was found. When the analyses presented above were conducted using disease-free retinas as a control group, the relationships between AMD and all lens opacifying disease were stronger (higher estimates and tighter confidence limits).

The association between lens and macular disease independent of age is consistent with the theory of ultraviolet/near-ultraviolet light damage to the eyes. Until the actual risk factors for both conditions are clearly known, the most important implication of these findings is perhaps that surgical removal of cataracts, while improving vision in the short term, may actually place patients at greater risk of irreversible visual loss in the long run. With the increased life expectancy of the general population, this may become a serious problem, and warrants further investigation. The cheapest and most effective public health measure may be to encourage use of protective eyewear at early ages.

New Pamphlets Available on Coping with Alzheimer's Disease

Five new pamphlets designed to help people caring for someone with Alzheimer's Disease (AD) have been developed by the Alzheimer's Association of Greater Washington. Alzheimer's families face unique challenges, since most care for their family member at home. The new pamphlets provide practical, up-to-date information to help families cope. Each pamphlet covers a specific Alzheimer's issue:

- *Especially for the Alzheimer Caregiver* tells how to recognize and deal positively with the feelings of guilt, isolation and burn-out almost all caregivers experience. An Alzheimer care-provider's first priority should be to stay in good shape emotionally as well as physically.
- *Caregiving at Home* outlines the key practical issues involved in choosing to provide home care. It also provides many tips on safety, meals, personal care, leisure activities, and common behavioral problems.
- *Communicating with the Alzheimer Patient* examines how AD affects communication and explains many verbal and nonverbal techniques for helping the patient to communicate with and understand other people.
- *Financial Services You May Need* describes financial assistance and medical expense programs that can help a family meet the heavy cost of AD. It also tells what questions to ask, where and how to apply.
- *Directions in Alzheimer's Disease Research* discusses the latest findings about what causes AD, how it might be cured, what works to relieve symptoms, improving diagnostic methods and providing better care.

All the booklets indicate where to find more detailed information on specific issues. The set of five booklets is available from the Alzheimer's Disease Association of Greater Washington, 7970 Old Georgetown Road, Suite 4C, Bethesda, MD 20814. Include $2.00 for postage and handling.

Self-Reported Diabetes in Mexican Americans: HHANES 1982–84

ELISEO J. PEREZ-STABLE, MD, MARILYN MILES MCMILLEN, PHD, MAUREEN I. HARRIS, PHD, MPH, RUMALDO Z. JUAREZ, PHD, WILLIAM C. KNOWLER, MD, DRPH, MICHAEL P. STERN, MD, AND SUZANNE G. HAYNES, PHD

Abstract: In the Hispanic Health and Nutrition Examination Survey (HHANES) of 3,928 Mexican Americans ages 20–74 years, the age-adjusted prevalence of self-reported diabetes was 6.8 percent among men and 7.6 percent among women. Comparable age-adjusted rates for the US population in a national survey were 2.9 percent in men and 3.8 percent in women. The prevalence of diabetes in Mexican Americans is greater in older age groups, was similar in men and women, and among women only was inversely associated with education. (*Am J Public Health* 1989; 79:770–772.)

Introduction

Community-based studies have shown that Mexican Americans in Texas have a three- to five-fold increase in the prevalence of diagnosed and undiagnosed non-insulin dependent diabetes mellitus when compared to non-Hispanic Whites.[1–4] The higher prevalence of obesity,[1–5] the more centralized fat distribution,[6] and genetic factors related to admixture with the indigenous peoples of the Americas among Mexican Americans may partly explain this increased prevalence.[3] Diabetes may not only be more prevalent but also more severe in its manifestations in this population.[7–9]

This report presents data on self-reported diabetes from the Hispanic Health and Nutrition Examination Survey (HHANES) and compares them to data from the second National Health and Nutrition Examination Survey (NHANES II).

Methods

HHANES was conducted in the southwestern United States (Arizona, California, Colorado, New Mexico, and Texas) between 1982–84. A stratified probability sample of the civilian, noninstitutionalized Mexican origin population was generated using a four-stage process.[10] The weighted estimates presented in this report are representative of Mexican Americans in those five states. Details of the HHANES sample design, operational plan, and quality control procedures have been published.[11]

The adult sample person questionnaire interviews were conducted by trained bilingual interviewers in the person's household in either English or Spanish. Mexican Americans ages 20–70 were asked: "Do you have diabetes or sugar diabetes?" Persons answering yes were then asked: "Did a doctor tell you that you have it?" Those who responded yes to both questions were defined as having self-reported diabetes.[12]

The acculturation scale developed for use in HHANES was based on eight of 20 items selected from an acculturation scale developed by Cuellar, *et al*:[13] an average score of eight items is based on language orientation (Spanish to English is scored from 1 to 5) and ethnic identification (Mexican to "American" scored from 1 to 5). For the purpose of this analysis, tertiles were used to categorize the acculturation scores into low, middle, and high groups.

Data on self-reported diabetes from the second National Health and Nutrition Examination Survey (NHANES II), a national probability sample of non-institutionalized civilians, are used for comparison.[14–16]

Statistical Analysis

Age-adjustment was carried out by means of direct standardization, using the US 1980 Census population as the standard.[17] Standard errors of age-adjusted rates were estimated using SESUDAAN.[18] For age-specific rates, the variances were calculated using the assumption of simple random sampling and then adjusted by the average design effect (1.0 in this case).[19,20] Association of self-reported diabetes with education, income, and acculturation were tested by multidimensional contingency table chi-square analysis, controlling for age and sex.

Results

A total of 4,735 Mexican Americans ages 20 through 74 were selected for the survey, with 3,928 (83 percent) completing the diabetes section of the household questionnaire. Respondents had a mean age of 36 years and were evenly divided between sexes; 64 percent were born in the United States. The comparison population from NHANES II consisted of 17,390 selected sample persons ages 20–74 years, of which 15,357 (88.3 percent) completed the diabetes questionnaire.

The age-adjusted prevalence rate for self-reported diabetes in Mexican Americans ages 20 through 74 years was 6.8 percent among men and 7.6 percent among women. Comparable rates for the US population measured in NHANES II were 2.9 percent for men and 3.8 percent for women.[17]

The prevalence of self-reported diabetes in Mexican Americans was greater in the older age groups of both sexes (Table

1), as it was in the general US population.[17,18] There were no differences between rates in males and females within three of the four age groups of Mexican Americans, although prevalence in women 45 to 54 years of age was 1.8 times as high as in men. In comparison with NHANES II rates for each age group, self-reported diabetes was two to three times as prevalent for Mexican American men and women.

Increasing education among Mexican American women was associated with a significant decrease in age-adjusted rates of self-reported diabetes, but this difference was not noted among men (Table 1). The age-adjusted prevalence was higher in men with a middle tertile acculturation score (8.7 percent) than in those in the low (5.7 percent) or high (5.3 percent) tertiles. Family income was not associated with self-reported diabetes in either gender.

Self-reported treatment for diabetes was less common with insulin than with oral hypoglycemic agents (diabetes pills) in both Mexican Americans and the general population (Table 2). Adherence to special diets and to treatment with oral hypoglycemic agents was similar in the two populations. The proportion of Mexican American men who were aware of their diabetes, but not currently using any of these treatment alternatives, was considerably higher (40 percent) than reported by the NHANES II men with diabetes (27 percent).

Discussion

Because Mexican Americans are the fastest growing ethnic group in the southwestern states and diabetes is such an important contributor to morbidity and mortality in adults,[21] accurate information on prevalence is essential to public health authorities, clinicians, and community leaders.

The prevalence of self-reported diagnosed diabetes in adult Mexican Americans in HHANES is two to three times that estimated for White and Black adults in NHANES II and about twice the rate estimated for the general population from the 1982–84 National Health Interview Survey. Data from Bexar County, Texas, showed that compared with non-Hispanic

*Numbers of sample persons are shown for information only; data are weighted to the Mexican American population of the Southwest US.

Whites, Mexican Americans have a higher mortality due to diabetes[22] and a greater prevalence of self-reported diabetes.[23] Rates for self-reported diabetes in Mexican Americans in Starr County, Texas,[23] and participating in the San Antonio Heart Study[2] (Unpublished data, Michael Stern) are similar for corresponding age groups to the HHANES rates for the entire southwest US Mexican American population.

The San Antonio Heart Study[2–4] has found that the age-adjusted diabetes rates for Mexican Americans are highest for those living in the Barrio (13.7 percent for men and 14.8 percent for women) and lowest among those living in the more affluent suburbs (6.1 percent for men and 3.7 percent for women).[4] Lower rates of diabetes among Mexican Americans with greater affluence and/or acculturation, however, were not consistently observed in HHANES. A significant inverse relationship between self-reported diabetes and education was found for women but not for men. Men with middle tertile acculturation scores reported a greater prevalence of diabetes, and no significant relationship was found for family income after adjusting for age. A possible explanation for the discrepancy in these two studies is that the San Antonio Heart Study results are based on total diabetes rates (diagnosed and undiagnosed) and the HHANES data in this report include self-reported diabetes only. When oral glucose tolerance tests have been used in population studies, the total prevalence of diabetes nearly doubles. Thus the socioeconomic gradient of less diabetes with increasing affluence may be present only if undiagnosed cases are included. Less affluent Mexican Americans may have a greater prevalence of undiagnosed diabetes because they have less access to health care.

The HHANES results in Mexican Americans confirm the presence of a two- to three-fold greater prevalence of self-reported diabetes, and health care providers need to give a high priority to diabetes as a major health issue in this group. Future research comparing Hispanic subgroups may help explain the relative importance of socioeconomic, cultural, and genetic factors of this observation.

Black/White Differences in Non-treatment of Bladder Cancer Patients and Implications for Survival

WILLIAM J. MAYER, MD, MPH, AND WILLIAM P. MCWHORTER, MD, MPH

Abstract: Analysis of 20,764 White and 882 Black bladder cancer patients diagnosed during 1978–85 indicates that Black patients were more likely than White patients to go untreated following diagnosis after adjustment for age- and stage-at-diagnosis, sex, and tumor histology (OR = 1.80, 95% CI = 1.33, 2.43). Treatment status was found to be a significant predictor of five-year survival after adjustment (treated/untreated odds ratio = 3.16, 95% CI = 2.08, 4.79). Results suggest that differences in initial therapy may contribute to the survival differential between Black and White bladder cancer patients. (*Am J Public Health* 1989;79:772–774.)

Introduction

Decreased survival in Black patients relative to White patients with bladder cancer has been documented in several reports.[1–8] A number of factors have been found to contribute to this survival difference: age, diagnosis at more advanced stages, and more aggressive tumor histology. Within stage- and histology-specific groups, Blacks continued to have poorer five-year relative survival rates.[5,8] Findings by Axtell and Myers[7] suggest that different treatment patterns could also explain some of the racial differences in survival.

Questions remain regarding differences in treatment with respect to such determinants as age, stage at diagnosis, and histologic type, and their role in poorer survival among Black relative to White bladder cancer patients. We attempted to answer these questions through the study of a marker for treatment differences—non-treatment—and its association with survival in 20,764 White and 882 Black bladder cancer patients diagnosed between 1978 and 1985.

Methods

This study is based upon data collected by nine population-based tumor registries participating in the National

From the Division of Cancer Prevention and Control, National Cancer Institute. Address reprint requests to Dr. William J. Mayer, NCI/DCPC, Executive Plaza North, Suite 241, 9000 Rockville Pike, Bethesda, MD 20892.
This paper, submitted to the Journal March 25, 1988, was revised and accepted for publication January 4, 1989.

Cancer Institute's SEER program (Atlanta, Connecticut, Detroit, Hawaii, Iowa, New Mexico, San Francisco-Oakland, Seattle-Puget Sound, Utah).[9] The variables in this study are determined in the SEER registries by review of hospital, clinic, private laboratory, private radiotherapy, private surgery, private practitioner (where the hospital record indicated therapy was to be received from the private practitioner), and nursing/convalescent home records. Case finding audits are conducted to ensure complete coverage of the SEER areas, and periodic training sessions and workshops are held to maintain quality control.

For this analysis, only patients with "Black" or "White" race noted in the medical record, and with newly diagnosed bladder cancer (ICD-0 188.0-188.9) as a single or first primary tumor were selected.[10] Excluded were 457 cases: patients diagnosed through death certificate or autopsy report alone (n = 49), patients with tumors not microscopically confirmed (n = 333), patients with unknown first course of therapy (n = 56), and patients with missing data for stage-at-diagnosis (n = 19). Using these criteria, 20,764 White and 882 Black bladder cancer patients were studied for racial differences in first course of therapy. Excluded cases had a somewhat higher proportion of patients who were older, Black, and female than did selected cases.* There were no other differences.

First course of therapy includes all cancer-directed therapy within four months of the initiation of therapy, which may occur at any time following diagnosis. A categorical, non-treated/treated variable was derived from the data. Black and White patients were then compared on this treatment status variable.

*Data available on request to author.

Survival time was defined as the period from the month of diagnosis as noted in the medical record to the earlier data of most current follow-up or December 1985, the most recent date for which virtually complete follow-up data were available.

Logistic regression analysis was used to explore the role of race in non-treatment of bladder cancer, adjusting for the potential confounding variables of age- and stage-at-diagnosis, sex, and tumor histology. This analysis was conducted for all study patients combined and separately by registry using the LOGIST procedure available through the SAS Institute.[12]

Because the proportional hazards assumption of a constant hazard ratio over time was not met by the data, logistic regression analysis was used to study the relation of treatment status with five-year survival with bladder cancer, simultaneously adjusting for race, age- and stage-at-diagnosis, sex, and tumor histology. This analysis was restricted to the 7,321 cases diagnosed between January 1978 and December 1980, and thus available for five years of follow-up. Of these patients, 4,254 were known to have survived for at least five years following diagnosis, and 3,067 were known to have died within five years of diagnosis. Cases diagnosed in this period alive at a most recent follow-up date less than five years after diagnosis were excluded from our analysis (n = 175). There was no difference between selected and excluded cases in the proportion of treated and untreated patients.

Results

Black and White, treated and untreated, bladder cancer patients are compared by age- and stage-at-diagnosis, sex, and tumor histology in Table 1. In the logistic regression (Table 2), Blacks were more likely than Whites to go untreated even with adjustment for age- and stage-at-diagnosis, sex, and tumor histology (O.R. = 1.80, 95% CI = 1.33, 2.43). A higher probability of non-treatment was also asso-

ciated with advancing age, unknown stage and advanced stage at diagnosis. Patients with papillary, transitional cell, and papillary-transitional cell histology were less likely to be untreated as compared to patients with tumors histologically identified as squamous cell or "other" (including: "adenocarcinoma NOS," "malignant NOS" and "cancer NOS").

This logistic regression model was also used to analyze our data by registry. The non-treatment odds ratio for Blacks versus Whites was 1.74 (95% CI = 0.79, 3.82) in Atlanta, 3.10 (95% CI = 1.50, 6.41) in Connecticut, 1.38 (95% CI = 0.84, 2.26) in Metropolitan Detroit, 2.66 (95% CI = 0.29, 24.51) in New Mexico, and 1.60 (95% CI = 0.72, 3.56) in San Francisco-Oakland. The results were not interpretable for four other SEER registries due to small numbers and/or limited variable dispersion among the cases.

In a logistic regression analysis of survival, the odds ratio for five-year survival with bladder cancer for treated versus untreated patients was 3.16 (95% CI = 2.08, 4.79), with simultaneous adjustment for race, age- and stage-at-diagnosis, sex and tumor histology (Table 3). Analysis by registry yielded similar results in the eight registries for which there were sufficient data. Use of a proportional hazards model also yielded similar results.

The effect of treatment/non-treatment status on racial differences in survival was small (data not shown) as would be predicted given that non-treatment was selected as only a marker for treatment differences, with a relatively small proportion of patients in the non-treatment category.

Discussion

The results of this study indicate that there are differences in treatment status between Black and White bladder cancer patients, using as an indicator the proportion untreated. Black patients were more than twice as likely as White patients to go untreated. This difference was only partially explained by racial differences in age- and stage-at-diagnosis, sex, or tumor histology.

Non-treatment was also associated with poorer five-year survival among bladder cancer patients, even after adjustment for race, age- and stage-at-diagnosis, sex, and tumor histology. Race was also found to be associated with five-year survival with bladder cancer, even after adjustment for non-treatment. Given that treatment/non-treatment status was selected for use only as a marker for treatment differences, with a relatively small number of patients going untreated, we would not have predicted that adjustment for this variable would have a substantial impact on Black/White differences in survival.

These findings suggest that differences in treatment status contribute to the survival differential between Black and White bladder cancer patients.

Potential sources of bias in our findings include the possibility of race-selective underreporting of patient treatment. Because surgery and radiation therapy have been the mainstays of treatment for bladder cancer,[13] it is unlikely that initial therapy would occur outside settings where SEER reporting is virtually complete—hospitals, or private surgical or radiotherapy facilities. In addition, a conservative bias may have been introduced in the non-treatment odds ratio for women versus men by the exclusion of proportionately more women from the patient population selected for the study.

This study was limited by the type of data routinely collected by the tumor registries participating in the SEER program. SEER data on stage at diagnosis and tumor histology may not adequately adjust for these variables, particularly since we were unable to rule out bias in physician diagnostic practices as recorded in the medical record. SEER registries report data on populations in which rural Blacks are underrepresented. Thus, these results should be generalized to rural populations with caution. Treatment of cases was reported to SEER only in the broadest of categories (e.g., "surgery only"). As a result we were unable to assess the quality of care for patients who received some form of initial therapy. Individual patient characteristics which might be expected to influence treatment such as concomitant illness, education, income, and source of medical care could not be included in our analysis as they are not routinely reported to SEER.

A more complete assessment is needed of Black/White differences in patterns and quality of bladder cancer treat-

ment, their biologic, socioeconomic, and behavioral determinants, and their impact on survival. The National Cancer Institute is currently conducting a multicenter investigation of Black/White cancer survival differences that will further our understanding of these issues.

Factors Associated with Participation in a Community Senior Health Promotion Program: A Pilot Study

DAVID M. BUCHNER, MD, MPH, AND DAVID C. PEARSON, PHD

Abstract: Factors associated with participation in a community senior health promotion program were studied in 103 participants and a population-based control group of 531 non-participants. Compared to controls, participants had similar physical health status, but lower mental and social health status. Both men and women participants reported more depressive symptoms, lower positive affect, and lower social participation. Mental and social health may be important yet under-studied factors influencing participation in community health promotion programs. (*Am J Public Health* 1989; 79:775–777.)

Introduction

The results of large health promotion/disease prevention (HPDP) research projects[1–8] suggest HPDP programs attract relatively healthy persons in higher socioeconomic groups. But little is known about factors influencing participation in the community-based programs unaffiliated with a major research project—the setting in which the majority of health promotion/disease prevention programs presumably must occur. Also, few HPDP programs have studied recruitment of elderly subjects. For these reasons, we studied factors associated with participation in a community-based, senior health promotion program sponsored by a large health maintenance organization (HMO).

Methods

The study was conducted at Group Health Cooperative of Puget Sound (GHC), a large, closed panel, not-for-profit HMO in western Washington State. The health promotion/disease prevention (HPDP) program (Growing Healthier) was intended for a broad target population of older adults and was advertised through the GHC magazine mailed to all enrollees, brochures distributed at GHC clinics, and presentations to consumer groups. The program was described as an opportunity to "enjoy life more" and "take greater control of your health and future." The curriculum consisted of a 10-week series of lectures, group discussions, and skills demonstrations led by trained instructors and senior volunteers. Specific topics covered included exercise, nutrition, stress management, social support, and self-responsibility/self-assertiveness.

Study participants were 103 (98 per cent) of the first 105 older adults (age 55+) to enroll in the Growing Healthier program given in the fall of 1984 at three of the 21 HMO clinics. Controls were 531 respondents (age 55+) to a survey of a stratified random sample of HMO enrollees (response rate = 90 per cent) and did not attend the program. For the analysis, control data were weighted to approximate a simple random sample.

The sources and/or definition of the independent variables used in this study are shown in Appendix I. Odds ratios assessed the association between program participation and subject characteristics. For consistency, variables with more than two levels were collapsed down to two categories. Adjustment for potential confounders was done using logistic regression.

Results

Table 1 describes the demographic characteristics of the study sample. Almost all study subjects were White. Compared to controls, participants were older, better educated, and reported higher incomes.

[a]Control data adjusted so that it reflects a simple, random sample of HMO enrollees over age 54 (actual sample was a random sample stratified by age).

Participants and controls differed on several study variables (Table 2). Use of seat belts and owning smoke alarms were associated with participation, but owning home fire extinguishers and refraining from drinking prior to driving were unrelated to participation. Lifestyle was associated with participation differently for men and women. Exercise and non-smoking were more strongly associated with participation in men. Obesity and abstinence from alcohol tended to be associated with participation for men, but with non-participation in women.

The health status of the participants and controls did not differ significantly as measured by self-perceived general health or by the Alameda Health Status scale (a measure of physical health). Varying the cut points on these scales in the statistical analysis did not change this result.

The mental and social health status of both men and women participants were lower than controls. Participation rates were substantially higher in persons with low positive affect, low emotional ties, high depressive symptoms, and low social participation. Low social support was not as strongly associated with participation. With the exception of emotional ties, findings were consistent between men and women.

Adjustment for education, income, marital status, and residential status had little effect on results, even though education in particular was associated with participation (age- and sex-adjusted odds ratio = 1.5, 95% confidence interval = 1.3, 1.8). This suggested the observed differences between participants and controls were not simply a reflection of the higher socioeconomic status of participants.

Discussion

Several findings of this study were unanticipated. First, associations of lifestyle factors with participation appeared to differ according to sex. Second, the general and physical

health of participants were no better than that of controls; although a lack of power or of sensitivity in the measurement scales could explain this result, in several measures of physical health the trends were for participants to be less healthy than controls. Third, participants had significantly lower mental and social health status, although not so low as to imply major social or psychological problems. As Growing Healthier targeted (in part) older adults wishing to improve their mental and social health, this finding is a notable exception to the usual situation of difficulty reaching a HPDP target population.

In contrast, participants in large HPDP research projects have often been physically healthier,[1,7] and the few available data suggest participants also tend to be socially and mentally healthier.[1,5,8] Perhaps factors which influence participation in large HPDP research projects differ from those in small community HPDP programs. Indeed, community programs lack several potential barriers to participation found in research studies (e.g., chance of randomization to a control group, burden of data collection, commitment to long-term follow-up).

But additional research is necessary to appraise the generalizability of these results. Factors influencing participation are to some extent program specific,[9] so some differences among programs are expected. As health status measures of this study were chosen because they were short and self-administered, research is needed using more comprehensive measures measuring a variety of aspects of mental and social health. Also, about three-fourths of participants received their medical care from the three clinics where the Growing Healthier program was given. Our data lacked clinic identifiers for participants, so we could not exclude the possibility that differences between participants and controls were due to differences between these three clinic sites and other HMO clinics. However, analysis of control data did not suggest these three clinics differed systematically from other HMO clinics on study variables.

In summary, mental and social health status may be important determinants of participation in community-based HPDP programs. Community HPDP programs should consider the potential importance of their mental and social health content. HPDP program evaluations should include social and mental health status measures. Of interest is whether program efficacy and effectiveness vary according to the mental and social health status of participants.

APPENDIX I

Definitions of Independent Variables

Variables	Definition
Lifestyle	
Non-smoker	Not currently smoking cigarettes[10]
Non-drinker	No alcohol use in the past year[10]
Regular Exerciser	At least 20 minutes of exercise three times a week[10]
Overweight by >20%	Present weight greater than 120% of ideal body weight according to Metropolitan Life Tables
Home Car Safety	
Home Smoke Alarm	Smoke alarm(s) installed in the primary residence
Home Fire Extinguisher	Fire extinguisher present in the primary residence
Regular Seat Belt Use	Seat Belts usage reported as always or almost always (as opposed to never, rare, or sometimes)
Drinking Driver	Consumption of more than two drinks prior to driving an automobile in the past year[13]
Health Status–General	
Good/Excellent Health	Self-perceived health status was good or excellent (as opposed to fair or poor)
Health Status–Physical	
Low Alameda Score	Score of 1 to 4 on Alameda Health Status scale, indicating presence of at least one chronic medical condition (range of possible scores: 1 to 7)[12]
Heart Problems	Self-report of "heart trouble" in past year
Diabetes	Self-report of "diabetes" in past year
Emphysema	Self-report of "emphysema or chronic bronchitis" in past year
Arthritis	Self-report of "arthritis or rheumatism" in past year
Health Status–Mental	
Low Positive Affect	Score of 41 to 60 on Positive Affect Scale (ten questions, range of possible scores: 10 to 60)[11]
High Depression Symptoms	Score of 9 to 23 on Depression Scale (four questions, range of possible scores: 4 to 23)[11]
Low Emotional Ties	Score of 2 to 9 on Emotional Ties scale (two questions, range of possible scores: 2 to 12)[11]
Health Status–Social	
Low Social Support	Score of 4 to 7 on Social Support Scale (three questions, range of possible scores 1 to 7)[13]
Low Social Participation	Score of 2 to 3 on Social Participation Scale (two questions, range of possible scores: 0 to 3)[13]

New from nchs

Older People in the United States Who Receive Help with Basic Activities of Daily Living

MARY GRACE KOVAR, DRPH, GERRY HENDERSHOT, PHD, AND EVELYN MATHIS

There were about 28 million people in the United States who were age 65 or older in the mid-1980s. According to the US Bureau of the Census mid-level projection, there will be about twice as many, 59 million, by the year 2025.[1]

Two recent reports from the National Center for Health Statistics (NCHS), one based on nursing homes and their residents and the other on community-dwelling people, should help in planning for this increasingly large population of older persons. Together, these reports give a better profile of the population of elderly citizens who receive help with basic activities than has been available until now.

Data from the National Nursing Home Survey show that there were 1,318,000 individuals age 65 and older who were residents of nursing homes in 1985 (Table 1). Many of them were extremely old (45 percent were age 85 or older) because the rate of nursing home use is much higher among those who are age 85 and older than among the 65–74 or 75–84 age groups, as can be seen in Figure 1. Most of the nursing home residents required help with at least one basic activity and over half had difficulty with continence. Figure 2 compares the assistance required among the three age groups. The rates were consistently higher among those age 85 and older than among the younger residents.

The National Nursing Home Survey of nursing homes and their residents has been conducted three times: the first time was in 1973–74, the second in 1977, and most recently in 1985. The survey was based on a national (excluding Alaska and Hawaii) probability sample of nursing homes without regard to the level of care, whether they participated in Medicare or Medicaid, or whether they were licensed; board and care homes and residential care facilities were excluded.

Of 1,220 facilities selected for the sample, 57 were out of scope or out of business when the interviewer called; 84 did not participate. In the 1,079 participating facilities, five residents were selected from the list of residents in the facility on the night before the survey.[2] The member of the nursing staff most familiar with the patient's care answered the questions about the patient. Information was obtained for 97 percent of the 5,395 patients selected for this part of the survey.

TABLE 1—Number of Persons Age 65 and Older in the United States

Age (Years)	In the Community 1984	In Nursing Homes 1985
	(In thousands)	
65 and older	26,433	1,318
65–74	16,288	212
75–84	8,249	509
85 and older	1,897	597

SOURCE: References 2 and 6.

However, the majority of persons who have passed their 65th birthday are not in nursing homes. In general, these individuals are younger than those in nursing homes; only 7 percent of the 26,433 people over age 65 living in the community in 1984 were age 85 or older. Data from the Supplement on Aging to the 1984 National Health Interview Survey show that about 2 million people, 7.6 percent of those age 65 and older who were living in communities, were receiving help with one or more of the specified activities shown in Figure 3.[3] The oldest group, age 85 years or older, who were living in the community were much more likely to be receiving help than community dwellers in their sixties or seventies and were more likely to be incontinent.

FIGURE 3—Percent of Community Residents Age 65 and Older Who Receive Help with Some Activities of Daily Living

Survey (NHIS) and the Supplement on Aging (SOA) have been published by NCHS[4,5] and the NHIS has been described previously in this column. In brief, it is a continuing national survey of the health of people residing in households in the United States. In 1984, there were about 41,000 households in the sample; responses were obtained for 96.4 percent of them. The SOA was added that year to obtain information about older persons that had not been available previously from a national survey. All of the people age 65 and older and half of those ages 55–64 in responding households were included in the SOA sample; 96 percent participated in the SOA and 92 percent answered the questions for themselves.

The report from the National Nursing Home Survey[2] contains a great deal of additional information about the facilities, registered nurses, residents, and discharged patients. The estimated 19,100 nursing homes in the United States had 1,624,000 beds, and 794,000 full-time equivalent employees who provided direct health-related services to nursing home residents. There were 103,000 registered nurses, of whom 61,000 were full-time staff. The average per diem rate was $62 in Medicare certified facilities, $50 in Medicaid skilled, and $40 in Medicaid intermediate care facilities. For the 1,491,000 current nursing home residents, the median length of time they had been a resident was 614 days; for the 877,000 persons discharged alive, it was 70 days; for the 344,000 persons discharged dead it was 163 days.

Both residency in a nursing home and dependency in the community-living population are highly associated with age. The rate of nursing home residency was 18 times as high for people age 85 and over as for people ages 65–74. Comparable rates for receiving help with the specified activities among people living in the community were 5–6 times as high.

These high rates in very old aged are extremely important for planning because the age group defined as being age 85 and over is the age group whose size is increasing most rapidly. The number of people age 85 and over is projected to almost triple between 1985 and 2025—from 2,711,000 to 7,452,000 people.[1] Whereas they comprised 9.5 percent of the population age 65 and older in 1985, that figure is projected to be 12.7 percent in the year 2025.

The data from these reports, coupled with shortages of nurses, the relatively few children that people of the "baby-boom" generation have had, and the increasing involvement of women in the labor force, raise troubling questions about who will provide good care for an increasing number of dependent people if disability and dependency rates are not reduced through health promotion and disease prevention efforts and appropriate health care.

It is important to reduce these dependency rates because, if the current age-specific rates remain constant, the US could have 3.1 million persons residing in nursing homes in 2025, compared to 1.3 million in 1985; and we also could have 6.5 million people receiving help in one or more of the seven Activities of Daily Living for which information was collected on the Supplement on Aging compared to 2.5 million receiving such help in 1984.[6–8]

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health*, 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5668 or 5600. All advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. CD Resources

AIDS: INFORMATION AND EDUCATION WORLDWIDE

CD-ROM DATABASE IN FULL TEXT

This collection combines international, national and U.S. States' data on the many aspects of AIDS in their original, full text format. Study and compare detailed AIDS related information from all over the world.

WORLDWIDE SOURCES

- World Health Organization (WHO)
- U.S. Centers for Disease Control
- National Commissions on AIDS
- 45 U.S. Departments of Health
- Asia, Africa, Europe, North and South America
- Public, private and non-governmental organizations

COLLECTION OVERVIEW

The social aspects of AIDS: legislation, policy, costs, and education.
The biological aspects: epidemiology, blood testing, immunology, and etiology.
The resource aspects: training, procedures, programs, services, organizations, and bibliographies.

PURPOSE

- A medical reference tool: medical centers, schools, AIDS testing centers, family planning clinics.
- A legislative guideline: government offices, legislators, corporations, national AIDS commissions
- A research source: public and academic libraries, health and science writers.
- A social policy and/or program resource: planners, AIDS support groups, counselling centers, health and patient care administrators.

HARDWARE REQUIREMENTS

- IBM-PC XT, AT, or PS/2 compatible computer
- 640K RAM
- MS-DOS version 3.1 or higher
- CD-ROM player
- MS-DOS extension software

Application of Clearance Concepts to the Assessment of Exposure to Lead in Drinking Water

FREDERIC Y. BOIS, PHARMD, THOMAS N. TOZER, PHD, LAUREN ZEISE, PHD, AND LESLIE Z. BENET, PHD

Abstract: This paper explores the application of clearance concepts to environmental toxicology. Lead, for which a clearance of about 0.5 ml/min is estimated from published data, is chosen as an example. An index for the contribution of drinking water to total exposure is developed using these concepts. For lead, this index is shown to increase with the concentration of the metal in water; it is higher for children than for adults. At the maximum contaminant level (MCL) of 10 μg/L proposed by the US Environmental Protection Agency (EPA), the average contribution from lead in drinking water is estimated to be 7 percent. The contribution in children is about twice as great. At and above the current MCL of 50 μg/L, drinking water becomes a major source of lead exposure. (Am J Public Health 1989, 79:827–831.)

Introduction

Regulatory standards, developed to protect the public's health, usually take neither variability in exposure nor sensitivity of subpopulations explicitly into account. Furthermore, the contribution from a particular contamination source (e.g., drinking water) is typically not evaluated with respect to its impact on the overall human exposure. A simple approach based on clearance concepts can provide an index of interindividual sensitivity, as well as an indication of the contribution to exposure by a particular source. Although clearance concepts are familiar to most clinicians, they are utilized to a much lesser extent for regulating environmental contaminants. The purpose of this paper is to explore this potential application.

The example for our purpose is lead. The common sources of lead are: drinking water, by corrosion of lead pipes and lead solders; air from the combustion of leaded gasoline; and soils, from the degradation of lead paints.[1–3] The toxicity of lead in humans has been extensively studied.[4–14] Even at low levels, cardiovascular changes in children's learning and behavior abnormalities are among several effects that are of concern. To limit human exposure, the US Environmental Protection Agency (EPA) has set a drinking water standard of 50 μg/L.[15] The same standard has been recommended by the World Health Organization.[16] This limit and the new value proposed by the EPA for lead in drinking water (10 μg/L at the tap, 5 μg/L entering the distribution system)[15] are subsequently evaluated with respect to the contribution of this source of lead to overall exposure using clearance concepts.

Clearance Concepts

The extent of exposure to pollutants can be assessed in terms of the blood concentration. There are many determinants of this concentration, including both absorption and elimination. Clearance is the most useful of the elimination parameters. Knowing the blood concentration under steady-state conditions, the daily intake can be estimated or, conversely, the blood concentration can be predicted when the rate of intake is known. The former use of clearance is emphasized in this paper.

Clearance, CL, is the proportionality constant between the rate at which the body eliminates an environmental toxicant, and its blood concentration, Cb. Under steady-state conditions the rate of elimination is equal to the rate of intake, Rt. Clearance is then a parameter (assuming first-order elimination) that relates blood concentration to the rate of intake; that is,

$$\text{Rate of intake} = Rt = CL \cdot Cb \qquad (1)$$

Consider a constant concentration, Cw, of lead in the water supply. The rate of intake of lead from drinking water, Rw, is the product of three terms: F, its availability or fraction absorbed into the general circulation, Qw, the water volume intake per day, and Cw. At steady-state, when water is the only source of exposure to the contaminant,

$$\text{Rate of intake} = Rw = F \cdot Qw \cdot Cw = CL \cdot Cb$$

or

$$Cb = (F \cdot Qw \cdot Cw)/CL \qquad (2)$$

Thus, under steady-state (or chronic) conditions the lead blood concentration is a function of water intake, lead concentration in the water supply, and lead blood clearance. Clearance is a property of both the administered compound and the individual receiving the compound.

Clearance concepts can be used to assess the contribution of a given source to the total exposure to a substance. Another use is to determine interindividual variability in both the exposure of handling of a toxicant. A third application is to aid in the determination of hazardous levels of toxicants. The first of these applications follows.

Given an estimated clearance value for a compound (CL_{ref}), measurements of blood concentrations in a local population, and drinking water concentrations to which the population is exposed, one can determine the fraction of total intake that can be attributed to drinking water. This fraction, Iw, is an index of contribution of drinking water to the input from all sources ($CL_{ref} \cdot Cb$):

$$Iw = Rw/Rt = (F \cdot Qw \cdot Cw) / (CL_{ref} \cdot Cb) \qquad (3)$$

This ratio ranges theoretically from 0 to 1.

Methods

Determination of Total Blood Lead Clearance

For analysis of isotopic tracer lead experiments, in which total input was controlled, equation 2 was used. When exposure to lead was not strictly controlled, the relationship between lead concentrations in blood and drinking water were determined by least-square regression, using a modification of equation 2. In this case, the rate of total lead intake Rt is comprised of two terms: a known exposure term Rw (through drinking water) and another term Rc accounting for concomitant (e.g., airborne, occupational, exposures.

According to equation 1:

$$\text{Rate of intake} = Rw + Rc = F \cdot Qw \cdot Cw + Rc = CL \cdot Cb$$

or

$$Cb = (F \cdot Qw/CL) \cdot Cw + Rc/CL \qquad (4)$$

Rc can be considered to be independent of Rw and the slope of the regression line of Cb on Cw gives CL/F.

Determination of the Index of Contamination

Equation 3 was used for all these determinations. The water and blood concentrations were obtained from the reports cited. Literature values[17] of water volume intake per day—2 L for adults (over the age of 15), 1.4 L for children, and 0.9 L for infants (under the age of 2)—were used. Values of 20 percent for adults and 40 percent for children and infants were assumed for the fraction absorbed F. These values are based on studies of the absorption of small amounts, less than 500 μg/day, of lead given orally in the diet. Absorption was on the order of 10 percent for normal, non-fasting adults[18] while, on an empty stomach, absorption can be 35 percent.[19] For children and infants, oral absorption has been observed to be higher, 40 to 50 percent.[2,20,21] These values can vary considerably from one individual to another.[20]

The reference clearance for children and infants has been obtained by scaling the value for a 70-kg adult using the empirical relationship:

$$CL_{ref}(\text{child}) = CL_{ref}(\text{adult}) \cdot [(\text{Body weight in kg})/70]^{0.7} \qquad (5)$$

This relationship corrects for differences in renal function under the assumption that lead clearance varies directly with renal function.[22]

The relationship between lead concentration in water and the index of contamination has been assessed by least-square regression. The difference between children and adults was tested by analysis of variance with a 5 percent significance level.

Results

Blood lead clearance and the contribution of drinking water to the total exposure of various populations, for which sufficient data are reported, are as follows.

Reference Value for Blood Clearance: Experimental Determination

Two sets of controlled experiments allow for a determination of reference values for blood lead clearance (see Table 1).

The first set of value is based on experiments previously performed.[23–29] Three male subjects were administered fixed amounts of lead in water drunk with each meal, for one to three years. Steady-state concentrations were reached. Data included the administered dose (300, 1000, or 2000 μg Pb/day), estimates of lead contained in the diet (derived from diet samples), as well as measurements of blood lead concentrations before and after exposure. The regression of blood lead concentration on daily intake gives a clearance estimate (inverse of the slope) of 0.7 ml/min (0.14 S.E.) assuming that, on average, 20 percent of the lead ingested is absorbed (i.e., F = 0.2). This calculation takes into account lead contributions from other sources, which were not controlled during the experiment itself.

TABLE 1—Blood Clearances for Lead Determined from Experimental Data of the Literature

Clearance (ml/min)	Remarks	Reference
0.7 ± 0.14	Subjects SW, MR, and EB	23–29
0.392	Subject — A	18,30
0.570	— B	—
0.324	— D	—

In the second set of experiments in human subjects,[18,30] ^{204}Pb nitrate was added in the diet. Experiments on three subjects lasted 104, 124, and 83 days, respectively. Although these exposures were of shorter duration than for the subjects of the first set of experiments, blood lead concentration-time profiles showed that steady-state conditions were nearly attained. Rather than supplementing the diet with lead, a fraction of the normal dietary intake of 300 μg/day was replaced with ^{204}Pb. Under these conditions, clearances were 0.392, 0.570, and 0.324 ml/min, respectively, for the three subjects with a mean value of 0.429 (coefficient of variation: 17 percent).

Lead Clearance Estimated from Epidemiological Surveys

Alternatively, lead clearance may be estimated from epidemiological studies in which individual lead concentrations in blood and drinking water are surveyed. Table 2 presents values obtained for various data sets using linear regression.

A regression performed on the first set of data[31] indicates a clearance of 0.44 ml/min (0.008 Standard Error) for males and 0.38 ml/min (0.008 SE) for females in a French population (correlation coefficient: 0.97). Exposures corresponded to lead concentrations in drinking water ranging from 0 to 400 μg/L, with a geometric mean of 160 μg/L.

Lacey, *et al*, analyzed the relationship between water lead concentration and blood lead in three-month-old infants.[32] The slope they determined corresponds to a clearance of 0.36 ml/min (0.07 S.E.); the correlation coefficient

TABLE 2—Blood Clearances for Lead Determined from Regressions of Published Epidemiological Data

Clearance (ml/min)	Standard Error (%)	N	Remarks	Reference
0.44	2	121	Males	31
0.38	2	132	Females	—
0.36	22	104	Infants	32
0.44	10	881	Males	33
3.8	NA	109	Females	34
1.8	NA	75	First draw water	35
1.2	NA	75	Running water	—

(NA: not available)

was not reported. Water lead concentration ranged from 0 to 600 μg/L. Total water intake was approximately 0.8 L/day, including water taken in infant formula. It is important here to correct for water intake and increased lead absorption in children (F = 0.4).

Blood and water lead levels in 24 British towns have been reported.[33] Mean water concentrations for the different towns ranged from 0 to 350 μg/L. In this concentration range the clearance is 0.44 ml/min (0.045 SE) and the correlation coefficient is 0.98.

A clearance of 3.8 ml/min is indicated in another source.[34] The standard deviation cannot be estimated from the data presented; it should be large, as indicated by a low correlation coefficient (0.36). It is also not certain how the points were weighted in the regression. Both these limitations apply to a further source of data[35] for which clearance values of 1.8 and 1.2 ml/min are estimated when first flush or running water samples, respectively, were used for assessing exposure. Correlation coefficients here were 0.76 and 0.72, respectively.

With the exception of the data from the earliest studies,[34,35] there is general agreement between the regression data and the values observed in controlled experiments. A blood clearance for lead of 0.5 ml/min for a 70-kg adult, with a range of 0.3 to 0.8 ml/min, therefore, seems reasonable. This value is used in the next section for determining the importance of lead in drinking water to an individual's overall exposure.

Contribution of Drinking Water to Total Exposure

The literature on lead measured in both an individual's blood and drinking water has been surveyed.[31,35–50] This survey is available from one of the authors (Tozer) upon request. These data allow estimation of *Iw* values.

The calculated index values range from 0.005 (0.5 percent) to 6.4 (640 percent) (values higher than 1 at high exposure may result from overestimation of the fraction absorbed or an underestimation of clearance). Figure 1 shows the frequency distribution of Iw; for 50 percent of the population, drinking water contributes at least 15 percent to the total exposure to lead, at least in our sample data. Figure 2 presents the relationship between Iw and the corresponding lead water concentration (in μg/L). Because of the apparent log-normal distribution of Iw and water lead concentration, the regression was performed using natural logarithms. When several measures of water lead concentration (e.g., first flush or running samples) were provided for the same population group, the median value was selected. The correlation coefficient for the regression was 0.90.

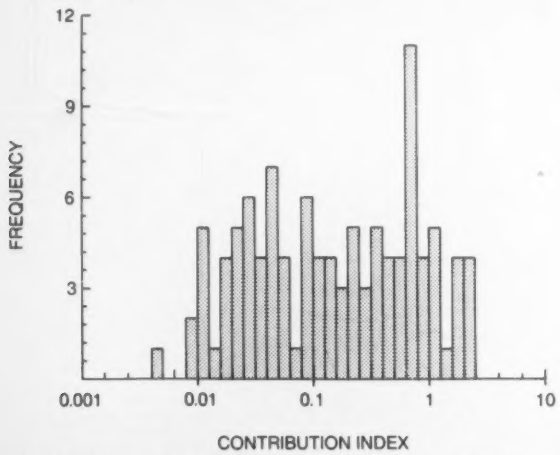

FIGURE 1—Distribution of the Index Iw of the Contribution of Lead in Drinking Water to Total Exposure, Determined from Epidemiological Data of the Literature (The Iw values are presented on a logarithmic scale).

Discussion

A clearance value obtained under steady-state conditions can be a useful indicator of the relative importance of chronic exposure to an environmental contaminant. Yet this concept has limitations and cannot be universally applied to all chemicals under all circumstances. As an example, consider compounds which are rapidly metabolized and/or excreted in the urine. A dynamic equilibrium is reached in which the blood concentration fluctuates dramatically over the day as a result of discontinuous intake (for drinking water) and high clearance. The proper assessment of a blood concentration would be difficult in this case. Lead, with its low clearance, does not fall into this category.

When a metabolite is primarily responsible for the toxicity, the use of the clearance of the parent compound as an indicator of individual sensitivity may be misleading. For example, a high clearance, for a given parent compound, could reflect a high rate of metabolite formation rather than a high renal excretion. This would imply an elevated target tissue dose, exactly contrary to what might be expected for the clearance value of the parent compound. Again, lead is not subject to this limitation.

Ideally the use of clearance concepts requires steady-state conditions and the presence of linear kinetics for distribution and disposition of the compound throughout the range of experimental and environmental exposures. For the majority of environmental contaminants, the assumption that levels of chronic exposure to a substance in air or water are

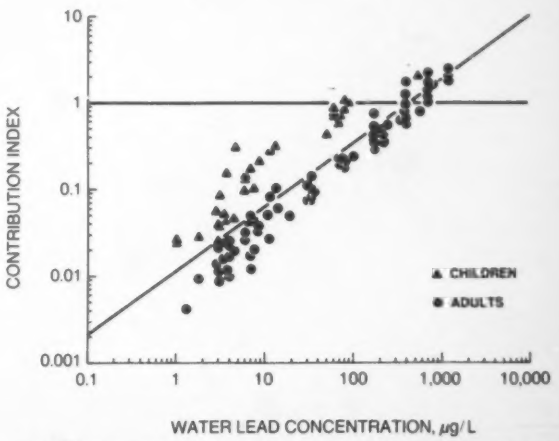

FIGURE 2—Regression of the logarithm of Iw on the logarithm of the lead concentration in water.
Data were obtained from published data in the literature. The regression equation is: ln (Iw) = −4.38+0.731·ln (lead concentration). The standard errors for slope and intercept are 0.0354 and 0.139, respectively. The correlation coefficient is 0.896.

below the values at which nonlinear behavior is observed is probably reasonable.

A nonlinear relationship seems to exist between blood lead and water lead concentrations at high exposures for humans.[33,36] Animal data indicate a possible saturation of blood lead levels.[52–54] Nevertheless, below approximately 500 μg/L the form of the relationship is nearly linear.[32] A clearance of 0.5 ml/min for adults is valid in this domain, and so are the results presented in Figures 1 and 2. Above 500 μg/L, Iw will be somewhat overestimated. A more mechanistic model[55–57] may more adequately describe the saturation of blood lead at high exposures. Two uptake mechanisms seem to be implied in intestinal lead absorption: a passive, non-saturable mechanism, and an active, saturable one.[5] A biphasic relationship between water lead and blood lead would be expected in this case. In this sense, the fact that the experimental clearance value determined in reference 23 (0.7 ml/min) is higher than that reported by Rabinowitz, *et al*,[18] could be explained by the much higher exposure in the former study.

Epidemiological studies may be used to estimate clearances through regression analysis. But high clearance values can be calculated if the intake of contaminated water is overestimated, for example by assuming a value of 2 L/day when the real value is much less. This situation may apply to the studies by Sherlock, *et al*.[49] A correct assessment of effective exposure is thus critical and a large population should be used.

Figure 2 shows that the contribution of lead in water to total lead exposure increases with its concentration at the tap. This relationship only occurs if the concentration of lead in drinking water correlates poorly with other sources of exposure and if drinking water is a major source of exposure. The lack of correlation of drinking water with other sources has also been reported.[50]

The spread about the regression line is quite large: the 95 percent confidence interval for estimates of Iw, at a given water concentration, span over a factor of 17. Therefore, for any particular water concentration the contribution of water to the total lead exposure cannot be calculated with accuracy. This variability may be explained by two factors. First, exposure is variable because water consumption is very different from user to user. We assumed standard values for different age groups.[17] Second, interindividual variability in lead absorption, distribution, and elimination clearly depends on individual factors.

It is not possible, in the absence of individual water consumption data, to separate these two sources of variation. To obtain a measure of interindividual variability, or identify different sensitive sub-groups, such information would be required. Nevertheless, in nearly all cases, the contribution of water to the overall exposure of lead is higher in children than in adults for the same water lead concentration. The fact that their intestinal absorption is higher by a factor of two contributes, together with their relatively higher water consumption, to this effect.

Note that for one-half of the population surveyed, waterborne lead represents less than 15 percent of the total exposure. The water for these populations contained only 30 μg/L or less of lead. When water lead concentration reaches 350 μg/L, on average 90 percent of total lead exposure arises from water. At the EPA MCL, 50 μg/L, about 20 percent of lead exposure in these populations is accounted for by lead in drinking water. However, at least 72 percent of lead exposure for 5 percent of the population might come from water contaminated with 50 μg/L of lead. This assumes a log-normal distribution (SE = 0.73) of *Iw* around the regression line.

We did not assume a dependence of lead clearance on urine flow. Under this hypothesis, the ratio Qw/CLref (in equation 3) would tend to have the same constant value for both adults and children. Such a flow dependence occurs when substances are extensively reabsorbed in the kidney tubules. Although lead seems to be partially reabsorbed,[58–61] renal clearance is not the only mechanism for lead elimination and the published data on renal lead handling in humans[62] suggest that lead clearance is not highly dependent on urine flow. To determine the impact of this flow hypothesis, we analyzed the effect of flow dependence. The difference between adults and children was reduced but still statistically significant.

ADDENDUM

Detailed lists of water lead concentrations and contribution index, Iw, of water to total exposure as determined from published epidemilogical data are available upon request to the authors.

Baby Doe Decision-Making in the 1990s: Conference Announced

A national conference entitled "Baby Doe Decision-Making in the 1990s" has been scheduled for September 14–15, 1989 at the Center for the Study of Bioethics, Medical College of Wisconsin, Milwaukee. Topics will include the effects of cost constraint measures, fetal therapy, genetic screening, and AIDS on Baby Doe decision-making.

The conference—co-sponsored by the Wisconsin Ethics Committee Network, the Medical Ethics Resource Network of Michigan, the Minnesota Network for Institutional Ethics Committees, and the Iowa Hospital Association—will be held at the Sheraton Mayfair Hotel in Milwaukee, WI.

For further information, contact: Anne Marie Talsky, Center for the Study of Bioethics, Medical College of Wisconsin, 8701 Watertown Plank Road, Milwaukee, WI 53226. Tel: 414/257-8498.

Survival Analysis of Hemophilia-Associated AIDS Cases in the US

JEANETTE K. STEHR-GREEN, MD, ROBERT C. HOLMAN, MS, AND MAUREEN A. MAHONEY, MT*

Abstract: Using national hemophilia-associated AIDS (acquired immunodeficiency syndrome) surveillance data and the life table method of survival analysis, the median length of survival of hemophilic patients in the United States after the diagnosis of AIDS was 11.7 months; the cumulative probability of survival at one year was 49.2 ± 2.0 percent; at two years, 28.9 ± 2.3 percent. Patients 13–29 years of age at the time of diagnosis had the longest survival and those 60 years and older had the shortest. Patients diagnosed since 1986 survived longer than those diagnosed before 1986. Length of survival did not differ significantly by race, coagulation disorder, AIDS manifestation at the time of diagnosis, or region of residence. Seven patients survived more than 36 months after AIDS was diagnosed. These patients were similar to those surviving for a shorter duration except that they were more likely to have met only the 1987 revision of the Centers for Disease Control AIDS surveillance case definition (as opposed to the 1985 case definition). Results of this study suggest that survival among hemophilic patients after the diagnosis of AIDS is similar to that reported by other investigators for other AIDS risk groups, excluding patients with Kaposi's sarcoma. (*Am J Public Health* 1989; 79:832–835.)

Introduction

The natural history of human immunodeficiency virus (HIV) infection in persons with hemophilia and other coagulation disorders is not well established and may differ from that in other acquired immunodeficiency syndrome (AIDS) risk groups.[1–3] Differences in the route and frequency of exposure to HIV, differences in the prevalence of potential cofactors for the development of AIDS (e.g., coexistent infections), and differences in routine medical care could lead to a variation in disease progression and ultimate outcome, such as survival. Using national surveillance data for hemophilia-associated AIDS, we examined the survival of hemophilic patients in the United States following the diagnosis of AIDS.

Methods

National surveillance of AIDS in persons with hemophilia and other coagulation disorders is maintained through the receipt of standardized AIDS case report forms submitted by individual state health departments to the Centers for Disease Control (CDC).[4] CDC personnel obtain supplemental information, including update of living status, through routine telephone interviews with the treating physician, nurse, or public health worker.

Only patients with illnesses that meet the CDC surveillance case definitions for AIDS, as revised in 1985 and 1987,[5,6] are included in the analyses. To be classified as having hemophilia-associated AIDS, the patient must have received blood or blood components since 1978 as treatment for a dysfunction in the normal coagulation system. Patients with multiple risk factors for HIV infection (i.e., risk factors in addition to a coagulation disorder, such as a history of male to male sexual contact or intravenous drug use) were excluded from the analyses (n = 24). Only patients reported before August 31, 1988 are included in the analyses.

The date of AIDS diagnosis was defined as the date the first AIDS-indicator disease (i.e., opportunistic infection or cancer meeting the CDC AIDS case definition)[5,6] was diagnosed. Survival time in months for each individual was calculated from the month of AIDS diagnosis to the month of death, if the patient had died, or from the month of AIDS diagnosis to August 1988, if the patient was still alive. Because length of survival was expressed in month intervals, the life table method of survival analysis was used to estimate the survivorship function from censored data.[7] The version of the Kruskal Wallis or generalized Wilcoxon test proposed by Breslow was used to compare the distribution of survival among patient subgroups.[8] CDC personnel obtained additional information on patients surviving longer than 36 months after the diagnosis of AIDS, including development of subsequent disease, other reasons for immunosuppression, and use of anti-HIV therapies, through telephone interview of the patient's physician, nurse, or associated public health worker in June 1988. Median ages at diagnosis of these patients and those surviving shorter periods were compared using Wilcoxon rank-sum test.[9] The method of Thomas and Gart was used to calculate odds ratios and 95% confidence intervals for dichotomous variables.[10]

Results

Between January 1, 1981 and August 31, 1988, 716 cases of hemophilia-associated AIDS (with no other risk factors for HIV infection) were reported to CDC. Six hundred and twenty-eight (88 percent) patients had hemophilia A (factor VIII deficiency); 61 (9 percent) had hemophilia B (factor IX deficiency); 16 (2 percent), von Willebrand's disease; five (<1 percent), acquired inhibitor to factor VIII; two (<1 percent), factor VII deficiency; two (<1 percent), factor X deficiency; and one each factor V and factor XI deficiency. All except 18 (3 percent) patients were male. The median age at the time of AIDS diagnosis was 31 years; however, patients diagnosed before 1986 were significantly older than those diagnosed in 1986 or later (median age of 34 years vs 30 years, $p < 0.001$). Of the 716 patients, 611 (86 percent) were White; 46 (6 percent), Black; 47 (7 percent), Hispanic; nine (1 percent), Asian/Pacific Islander; and three (<1 percent), American Indian/Alaskan Native.

Living status and date of death were known for 714 patients. As determined by the life table method, median survival from the time of AIDS diagnosis was 11.7 months. The cumulative probability of survival at one year was 49.2 ± 2.0 percent and at two years was 28.9 ± 2.3 percent.

This paper, submitted to the Journal August 26, 1988, was revised and accepted for publication February 6, 1989.

Survival did not differ by race, coagulation disorder, or region of residence (Table 1). Patients 13–29 years of age at the time of AIDS diagnosis had a significantly longer survival than the older patients 30–59 years of age and ≥60 years of age (Table 1 and Figure 1). Patients <13 years of age and 30–59 years of age also had a significantly longer survival than patients 60 years and older.

Patients diagnosed with AIDS before 1986 had a shorter survival than those diagnosed in 1986 or later (Table 2). Because the number of patients in our study diagnosed with only one AIDS-indicator disease other than *Pneumocystis carinii* pneumonia or esophageal candidiasis was small, survival by AIDS-indicator disease was limited to these two diagnoses. No difference in survival was observed (Table 2). Survival did not differ by case definition used to diagnose AIDS (1985 vs 1987 revision of the CDC AIDS case definition) (Table 2). Because the median age at diagnosis was younger among patients diagnosed in 1986 or later, analysis of survival time by year of diagnosis was stratified by age group (Table 3). In each age group, patients diagnosed since 1986 had a longer survival.

Seven patients survived longer than 36 months after the diagnosis of AIDS (Table 4). All were male; six had hemophilia A. These patients were similar to the patients surviving for shorter periods with respect to age at AIDS diagnosis, sex, race, and coagulation disorder. They were more likely to have met only the 1987 case definition (diagnosed retrospectively) as opposed to the 1985 case definition (4/7 [57 percent] vs 122/709 [17 percent], odds ratio = 6.4, 95% CI = 1.1, 44.2). All seven had antibody to HIV. Only one had been cultured for HIV and was found to be positive. No strain typing had been attempted on any of the patients. Five of the seven had been treated with some form of anti-HIV therapy; unfortunately, similar data were not available for patients living for a shorter duration.

Discussion

Our study, including patients with hemophilia and other coagulation disorders exclusively, expands upon studies of the natural history of HIV infection among different groups

TABLE 1—Length of Survival after Diagnosis of AIDS among Hemophilic Patients by Patient Characteristics, United States, January 1981–August 1988

Characteristics	Number	Median Survival Estimate (in months)	Cumulative Probability of Survival at: One Year	Two Years

at risk for AIDS. Rothenberg, *et al*, analyzed data from 5,833 AIDS patients in New York City.[11] Median length of survival ranged from 9.4 months in patients with a history of intravenous drug use to 13.1 months in patients with a history of homosexual activity. Patients with both risk factors had a median survival of 10.1 months and those with other risk

TABLE 4—Seven Patients with Hemophilia-Associated AIDS Surviving Longer than 36 Months after AIDS Diagnosis

Patient	Age at Diagnosis	Date of AIDS Diagnosis	AIDS Indicator Disease	Comment
A	35	1/84	cryptococcal meningitis*	on prednisone for thrombocytopenia at time of meningitis; treated with AZT and acyclovir; still living**

*met 1987 CDC AIDS surveillance case definition only.
**as of June 1988

factors had a median survival of 8.5 months. In an analysis of 663 AIDS cases from the United Kingdom,[12] Reeves and Overton reported a median survival of 12.6 months in AIDS patients with a history of homosexual activity and 10.5 months in other transmission categories combined. Both studies found the most favorable survival among patients with Kaposi's sarcoma alone (25.0 and 15.0 months, respectively). Neither study was able to examine hemophilic patients separately. Our results suggest that survival among hemophilic patients with AIDS is comparable to that observed in other patient groups, excluding those with Kaposi's sarcoma. However, data from studies by Rothenberg and Reeves were collected in 1985 and 1987, respectively. Survival may have improved in these groups. In our study, survival improved over time. This improved survival could reflect changes in health care for AIDS patients including earlier diagnosis and institution of treatment of AIDS-indicator diseases, prophylactic treatment for some opportunistic infections (e.g., *Pneumocystis carinii* pneumonia),[13] and development of anti-HIV therapies such as azidothymidine.[14,15] To facilitate comparisons between patient groups, survival analyses should be repeated in other groups to determine the impact of more recent changes in health care.

Similar to studies by Rothenberg and Reeves, we found a decreasing length of survival after the diagnosis of AIDS with increasing patient age. It has been shown that antigenic stimulation causes increased replication of HIV which may lead to a more rapid development and progression of HIV-related disease.[16] Repeated exposure to factor concentrate (also a powerful antigenic stimulus),[17] exposure to environmental contaminants, and a higher prevalence of hepatitis B and sexually transmitted diseases (Stehr-Green JK: unpublished data) could lead to a more rapid progression of HIV infection among older hemophilic patients and a less favorable survival. A more rapid progression of infection could also explain the decrease in median age of hemophilia-associated AIDS cases over time, consistent with findings of Eyster, *et al,* which showed age to be a cofactor for AIDS independent of date of infection.[18]

The 1987 revision of the CDC AIDS surveillance case definition includes a broader range of AIDS-indicator diseases (including HIV dementia and HIV wasting syndrome), indicator diseases that are presumptively diagnosed, and elimination of exclusions due to other causes of immunodeficiency. The large proportion of long survivors with illnesses meeting only the 1987 revision seems to suggest that these illnesses may be associated with a more favorable survival than those included in the 1985 case definition. However, the illnesses included in the revision may allow the patient to be diagnosed with AIDS and reported to CDC at an earlier point in the progression of HIV-related disease. That is, the interval between infection and development of clinical manifestations of AIDS may be shortened, resulting in an apparent increase in the length of survival after the diagnosis of AIDS. Analyses of survival from date of infection to death could eliminate this potential confounder. Unfortunately, the date of seroconversion is not available for most hemophilic patients due to multiple exposures to potentially contaminated blood products.

$5 Million Awarded to States to Help Low-Income AIDS Patients Purchase Medicines

An additional $5,075,490 in federal funds from the Health Resources and Services Administration (HRSA) of the US Public Health Service was recently awarded to 26 states to help low-income AIDS patients obtain drugs that would prolong their lives. The Food and Drug Administration (FDA) has determined that three drugs prolong the lives of AIDS patients—azidothymidine (AZT), alpha interferon, and aerosolized pentamidine.

The funds were distributed on March 31 just before the authorizing legislation, Public Law 100-471, expired. Those eligible for assistance are low-income individuals not covered by Medicaid or private insurance. Each state determines eligibility. The 26 states receiving the funds are: Alabama, Alaska, Arizona, California, Colorado, Florida, Georgia, Idaho, Illinois, Indiana, Kansas, Kentucky, Maine, Massachusetts, Mississippi, North Dakota, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Tennessee, Texas, Utah, Vermont, and Wisconsin.

Of the total distributed, $5 million came from the transfer of fiscal 1989 funds appropriated for AIDS programs administered by the Office of the Assistant Secretary for Health and four Public Health Service agencies. The remaining $75,490 derived from jurisdictions that reported they would not be able to use by September 30, 1989 funds distributed last November under PL 100-471. At that time, HRSA distributed to the 50 states and other jurisdictions some $15 million including $5 million from a private pharmaceutical company. The drug reimbursement program began in fiscal 1987 when HRSA awarded $30 million to states. The latest distribution brings the total federal funds awarded under the AIDS Drug Program to $45 million.

Birthplace and the Risk of AIDS among Hispanics in the United States

Richard M. Selik, MD, Kenneth G. Castro, MD, Marguerite Pappaioanou, DVM, PhD, and James W. Buehler, MD

Abstract: To extend previous work showing that the risk of AIDS (acquired immunodeficiency syndrome) is higher in US Hispanics than in Whites who are not Hispanic, we compared US residents born in different Latin American countries. We computed the cumulative incidence (CI) of AIDS and the distribution of cases by mode of exposure. Cases were those reported to the Centers for Disease Control between June 1, 1981 and December 12, 1988, and populations specific for birthplace were from the 1980 census. The reference group was the White population that was not Hispanic, CI 25.7/100,000. We estimated a similar rate in Mexican-born persons (25.3/100,000). In the South and West, the rate in Mexican-born Hispanics was half the reference rate. In each US region, the CI of AIDS in heterosexual intravenous drug abusers (IVDAs) in Puerto Rican-born persons was several times greater than that in other Latin American-born persons. Puerto Rican-born persons were the only Latin American-born persons in whom most cases were in heterosexual IVDAs. The data suggest that resources for preventing AIDS in Hispanics are needed most in those of Puerto Rican ethnicity for AIDS related to intravenous drug abuse. (*Am J Public Health* 1989; 79:836–839.)

Introduction

The risk of acquired immunodeficiency syndrome (AIDS) is higher in US Hispanics than in Whites who are not Hispanic.[1,2] Since Hispanics are a diverse ethnic group, targeting public health resources for preventing AIDS in Hispanics would be improved by information on AIDS risks in different Hispanic ethnic subgroups. Because data on AIDS cases reported to the Centers for Disease Control (CDC) include country of birth but not country of ancestry, we investigated the variation in the risk of AIDS by country of birth.

Methods

We analyzed the 78,751 AIDS cases meeting the case definition[3] reported to CDC between June 1, 1981 and December 12, 1988 in residents of the United States (the 50 states and District of Columbia).* We classified persons with AIDS according to their race/ethnicity and country or territory of birth. We computed the cumulative incidence, the number of cases per 100,000 US population of the respective group (1980 US census),[4] and the relative risk (RR), the ratio of the cumulative incidence in a group to the cumulative incidence in Whites who were not Hispanic. The 99% confidence limits around RRs were approximated by the first-order Taylor series method.[5] Since census data were unavailable for birthplace by race/ethnicity, we estimated the population of US-born Hispanics as the difference between resident Hispanics and residents born in Latin America.

Analyses were stratified by geographic region (Northeast, Midwest, South, and West)[4] and by presumed mode of acquiring human immunodeficiency virus (HIV) infection.[6] To detect the effect of differences in the prevalence of the various means of acquiring HIV in different populations, we stratified only the AIDS patients by exposure category, not the populations.

Results

Of the 10,336 Hispanic persons with AIDS in the United States, 49 percent were reported to have been born in the United States, 37 percent in a specified Latin American country or territory, 1 percent in another specified country, and 4 percent in an unspecified foreign country; the birthplace of the remaining 10 percent was unreported. Of the 4,045 Latin American-born persons with AIDS in the United States, 94 percent were Hispanic.

The cumulative incidence of AIDS in all Hispanics was elevated (70.8/100,000), but was not elevated in persons born in Mexico (25.3/100,000) (Table 1). In the South and West, the cumulative incidence in Mexican-born persons and in US-born Hispanics (≥75 percent of whom were of Mexican ethnicity in those regions) were both lower than the reference rate, but in the Northeast and Midwest they were higher than the reference rate.

The pattern of risk by ethnicity was similar for AIDS in homosexual/bisexual men without a history of intravenous drug abuse, representing 61 percent of all cases. In addition, the cumulative incidence in US-born Hispanics was about the same as the reference rate in the nation as a whole and in the Midwest (where 70 percent of US-born Hispanics were of Mexican ethnicity). A similar pattern was seen for AIDS in homosexual/bisexual male intravenous drug abusers (IVDAs), representing 7 percent of all cases; the cumulative incidence in Mexican-born persons was less than the referent in the West and the nation as a whole, and similar to the referent in the other three regions.

For AIDS in heterosexual IVDAs, representing 19 percent of all cases, the cumulative incidence in Mexican-born persons was above the referent in the Northeast and similar to the referent elsewhere (Table 1). The cumulative incidence in US-born Hispanics and persons born in Puerto Rico and Cuba exceeded the referent in each region, but among those born in other Latin American countries the cumulative incidence was greater in the Northeast region only. In each region, the cumulative incidence was markedly greater in Puerto Rican-born persons than in persons born in Cuba, Mexico, or other Latin American countries.

In the nation as a whole, Puerto Rican-born persons were the only Latin American-born persons in whom most AIDS cases were in heterosexual IVDAs (Table 2). Among persons born in Mexico, Cuba, and other Latin American countries, the proportion of cases in heterosexual IVDAs was 10 percent or less. Among the Puerto Rican-born, the proportion of cases in heterosexual IVDAs ranged from 32 percent in the South and West to 52 percent and 61 percent in the Midwest and Northeast, respectively—proportions

that were several times greater than among the other foreign-born. In the Northeast, where 64 percent of US-born Hispanics and 57 percent of all Hispanics were of Puerto Rican ethnicity,[7] most AIDS cases in US-born Hispanics and in all Hispanics were in heterosexual IVDAs. Among residents of Puerto Rico (excluded from the above analysis), the pattern was similar: 54 percent of cases were in heterosexual IVDAs.

Discussion

Although the risk of AIDS is elevated in US Hispanics,[1,2] the present study shows that the risk in persons of Mexican ethnicity is similar overall to that in the reference group of Whites who are not Hispanic, but varies by region. This finding agrees with HIV-antibody test data on applicants for military service which show that in the West (where 76 percent of Hispanics are of Mexican ethnicity), the prevalence of HIV antibody in Hispanics (0.9 percent) is the same as that in Whites who are not Hispanic (0.8 percent) (RR = 1.1, 99% confidence limits = 0.7, 1.7).**

The high proportion of cases in heterosexual IVDAs found among Hispanics overall[5] primarily reflects the high proportion in persons of Puerto Rican ethnicity (birth or ancestry). The strong association between persons of Puerto Rican ethnicity and heterosexual IVDAs with AIDS may be related to the concentration of both in the Northeast region. Of all US residents of Puerto Rican ethnicity, 74 percent resided in the Northeast,[7] where 74 percent of heterosexual IVDAs with AIDS and 89 percent of Hispanic heterosexual IVDAs with AIDS also resided. The Puerto Ricans' geographic location at the center of the AIDS epidemic in heterosexual IVDAs could have exposed them to a greater

risk of IVDA-related AIDS. Nevertheless, even in the regions where Puerto Ricans are a minority of the Hispanic population, the cumulative incidence of AIDS in heterosexual IVDAs was higher in persons born in Puerto Rico than in those born in Cuba, Mexico, or other Latin American countries. This suggests that the higher cumulative incidence in persons of Puerto Rican ethnicity may be due to a higher prevalence of intravenous drug abuse or sharing of needles and syringes, independent of geographic region.

Alternatively, Puerto Rican IVDAs outside the Northeast are likely to visit or be visited by other Puerto Ricans from the Northeast or from Puerto Rico itself, where most Hispanic persons with AIDS are IVDAs and the prevalence of HIV infection is high. HIV-antibody test data on applicants for military service show that the prevalence of HIV antibody in residents of Puerto Rico (0.6 percent) is almost as high as that in Hispanic residents of New York City (0.7 percent) and greater than that in residents of the United States as a whole (0.1 percent) or any of the 50 states.[8]*** Even without a higher prevalence of intravenous drug abuse, sharing needles and syringes with persons from the Northeast or Puerto Rico could account for Puerto Ricans in the Midwest, South, and West having higher cumulative incidence and higher proportions of AIDS cases in heterosexual IVDAs than other Hispanics outside the Northeast region.

Our estimates of cumulative incidence in persons born in Mexico, Cuba, and other Latin American countries may be too high, because as many as one million undocumented Hispanic aliens may not have been counted in the 1980 census.† Despite this possible bias, Mexican-born persons in the South and West had a lower cumulative incidence than White non-Hispanics. This possible bias is less likely to apply to persons born in Puerto Rico, as their US citizenship gave them no motive to avoid participation in the US census.

We have no data on the country of ancestry of US-born Hispanics with AIDS. It would be useful to know whether patterns of AIDS risk according to ancestry follow those according to birthplace. The high cumulative incidence and high proportion of cases in heterosexual IVDAs among

***Unpublished data on tests done from October 1985 through December 1987, US Department of Defense.

†Personal communication: Karen Woodrow, Bureau of the Census.

US-born Hispanics in the Northeast (where 57 percent of the Hispanic population is Puerto Rican) and the low cumulative incidence and low proportion in heterosexual IVDAs among US-born Hispanics in the West (where 76 percent of the Hispanic population is Mexican) suggest that the patterns are similar. If so, strategies for preventing AIDS[9–11] in US-born Hispanics should be similar to those for non-US-born Hispanics. Our data for the latter suggest that resources for preventing AIDS in Hispanics are needed most in those of Puerto Rican ethnicity, particularly for AIDS related to intravenous drug abuse.

3rd International Conference on AIDS Education: Call for Abstracts Extended to July 7

"Changing Environments: Meeting the Challenge" is the theme for the 3rd International Conference on AIDS Education, to be held September 10–13, 1989 in Nashville, Tennessee. The conference is sponsored by the International Society for AIDS Education and several other international and national organizations.

The main purpose of the conference is to bring together persons from academic, governmental, and community settings who are working in the interdisciplinary field of AIDS education, counseling, and prevention. Conference participants will review current approaches and methods in the context of meeting the challenges posed by changing social, economic, and institutional environments, as well as changing communication and information technologies. The adaptation of AIDS education and counseling programs to such change will be emphasized. Policy, psychosocial, legal, and ethical issues will be addressed.

The format of the conference will provide structured and unstructured periods for networking and idea exchange as well as plenary sessions featuring experts in the field. Concurrent sessions will be classified into three groups: Research Seminars, Roundtable Discussions, and Workshops. A Poster Session will further enhance knowledge and networking. Informal networking will occur during breaks, social events, and in the exhibits area.

The call for abstracts has been extended to include abstracts postmarked by July 7, 1989. To obtain an abstract form or additional information, contact: Conference Secretariat, 3rd International Conference on AIDS Education, P.O. Box 582, Vanderbilt University Medical School, Nashville, TN 37232-2351 USA. Tel: (615) 322-2437 or (615) 433-2252.

HIV Testing in Prisoners: Is Mandatory Testing Mandatory?

Jon K. Andrus, MD, David W. Fleming, MD, Catherine Knox, MN, Robert O. McAlister, PhD, Michael R. Skeels, PhD, MPH, Robert E. Conrad, PhD, John M. Horan, MD, MPH, and Laurence R. Foster, MD, MPH

Abstract: We studied 977 newly incarcerated Oregon inmates to compare voluntary versus mandatory human immunodeficiency virus antibody (HIVAb) testing in the prison setting. All inmates were offered HIVAb counseling and testing. Blood drawn for routine syphilis serology from those who declined this offer was also tested for HIVAb after personal identifiers had been removed. Only 1.2 percent (12) prisoners were HIV positive. However, 62.5 percent (611) inmates were at risk for HIV infection by being an intravenous drug user, a male homosexual, or hepatitis B core antibody (HBcAb) positive. The ratio of at-risk, as yet uninfected inmates to those already HIV infected was 53 to 1. Two-thirds of all inmates including those at-risk chose to receive counseling and testing. In areas where most at-risk inmates are not yet infected, it may be more appropriate for HIV prevention activities in prison to focus on voluntary programs that emphasize education and counseling rather than mandatory programs that emphasize testing. (*Am J Public Health* 1989; 79:840–842.)

Introduction

Persons for whom HIVAb (human immunodeficiency virus antibody) testing is already mandatory in the United States include immigrants, blood donors, and military recruits. Prison inmates comprise a population at risk for HIV infection. Many are intravenous (IV) drug users and all are entering a setting where homosexual sex may occur. The American Medical Association has recommended that "testing for AIDS virus should be mandatory . . . for inmates in federal and state prisons."[1] Currently, inmates in all federal prisons are tested. In 1986, three state prison systems required their prisoners to be tested for HIVAb; by 1988 this number had increased to 14.[2,3] However, little data have been available to evaluate the usefulness of mandatory HIVAb testing in the prison setting.

In 1987, the Oregon Health Division performed a study to evaluate the usefulness of a voluntary versus a mandatory HIVAb testing strategy in the Oregon corrections system.

Methods

All newly incarcerated inmates entering any of the five prisons of the Oregon State correctional system from September 1987 to January 1988 were enrolled in the study. Upon entry, each inmate was shown a 12-minute educational videotape on HIV infection and was then administered a standard questionnaire in private by a Corrections Department health care provider. Information collected from each inmate included: history of blood transfusion, sexual preference, IV drug history, self-assessed likelihood of HIV exposure, and HIV testing history. Additional information extracted from the records of inmates included: age, gender, race, education, crime, length of sentence, and history of sexually transmitted diseases.

All inmates were then offered confidential HIV antibody testing and counseling. Inmates were categorized into those choosing testing and those declining confidential testing. Inmates who declined were asked whether they would consider testing in the future if it could be offered in such a way that only they had knowledge of the results (anonymously). Those who would have considered anonymous testing were grouped separately from the rest of test decliners in some of the analyses.

Blood specimens from inmates choosing testing were tested for HIV antibody and results were presented to the inmate, along with post-test counseling. Blood specimens from all inmates are routinely drawn and tested for evidence of syphilis infection. Using these sera, a 95 percent random sample of all inmates declining testing was also tested for HIVAb in a blinded fashion after syphilis testing had been completed. These HIVAb results, with linked questionnaire data, were sent only to the Oregon Health Division. The study design was approved by the Oregon Health Division's human subjects review board, which included a medical ethicist, a lawyer from the American Civil Liberties Union, and representatives from prisoners, gays, and a community AIDS-prevention agency.

All specimens were also tested for hepatitis B core antibody (HBcAb). Hepatitis B and HIV infections are transmitted in the same way; we used HBcAb positivity as an objective, surrogate marker for a history of risk behavior for HIV infection. For purposes of this study, inmates were considered to be at risk for HIV infection if they had one or more of the following: IV drug use history, history of male homosexuality, or HBcAb positivity.

Serum specimens were tested at the Oregon Public Health Laboratory. HIV antibody testing was done using the Genetics Systems* enzyme linked immunosorbent assay. Repeatedly reactive sera were confirmed by the indirect immunofluorescence test. HBcAb tests were done using the Abbott* enzyme linked immunosorbent assay.

Black, Hispanic, and Native American inmates were grouped together as minority inmates. Male inmates were defined to have admitted homosexuality if they stated that they had ever had sex with men only or with both men and women.

All statistical tests were performed using the Epi Info computer software package provided by the Centers for Disease Control.

Results

Seroprevalence

A total of 995 consecutively admitted inmates were enrolled; 18 of the test decliners were randomly excluded from HIVAb testing. The mean age of the remaining 977 was 30 years (range 17 to 71 years), 91 percent male, 74 percent were White, 16 percent Black, 6 percent Hispanic, and 2 percent Native American.

Twelve inmates (1.2 percent) were HIVAb positive (Table 1).

Inmates who were HBcAb positive were more likely to be HIV infected (2.5 percent, 9/357) than those who were seronegative for HBcAb (0.5%, 3/620) (RR = 5.2; 95% CL 1.6, 16.7). Persons who admitted homosexuality or IV drug use were not more likely to be HIVAb positive than those who did not admit these behaviors, although the small number of HIV-seropositive inmates limited our power to detect a difference. The risk of HIV infection was not associated with other inmate characteristics studied, including race, education, history of previous HIV testing, crime, length of sentence, history of sexually transmitted diseases.

Risk Behavior and HIV Seroprevalence

Of the 977 inmates enrolled, 611 (63 percent) were HBcAb positive or reported a history of IV drug use or reported history of male homosexuality, and thus were at risk for HIV infection. This 63 percent does not include inmates who reported only a history of blood transfusion or sexually transmitted disease. Thus, 63 percent may be a conservative estimate of the proportion of inmates at risk for HIV infection. All 12 HIV positive inmates were in this group defined to be at risk. For every inmate infected, there were 53 others at risk, but as yet uninfected.

Test Choice

A total of 637 inmates (65 percent) chose to receive HIV counseling and testing. Of the 358 inmates declining testing, 98 (27 percent) would have considered anonymous testing, if it had been available.

Six of the 12 HIV-positive inmates voluntarily accepted an offer of confidential counseling and testing. HIV-positive inmates were not significantly different from HIV-negative inmates in the likelihood that they would choose to be tested confidentially. Among the 340 test decliners, 67 percent (4/6) of HIV-positive inmates would have considered anonymous testing compared to 28 percent (94/334) of HIV-negative inmates (RR = 2.4; CL 1.0, 5.4).

Test choice was not predicted by HBcAb status, admitted male homosexuality, age, gender, race, education, crime, and sentence. Seventy percent (361/519) of inmates who admitted to IV drug use accepted an offer of testing compared to 60 percent (276/457) of inmates who denied IV drug use (RR = 1.2; 95% CL 1.1, 1.3). Eighty-five percent (63/74) inmates who believed it likely that they had been exposed to HIV chose testing compared to 64 percent (566/885) of those who either did not believe or were not sure about HIV exposure (RR = 1.3; 95% CL 1.1, 1.6).

In this study, 35 percent (340/977) of the inmates declined the offer of confidential counseling and testing. Of those who declined, 56 percent (192/340) were at risk by being HBcAb positive, an IV drug user, and/or a male homosexual.

TABLE 1—HIV Seropositivity in Inmates by Demographic Characteristics and Risk Factors, Oregon, 1988

	Enrolled	HIV Seropositive (%)
Total	977	12 (1.2)
Sex		
Male	893	11 (1.2)

Male Homosexual	30	1 (3.3)
Unduplicated Total	611	12 (2.0)

Discussion

Both mandatory and voluntary testing strategies have their inherent limitations.[4,5] If the goal of testing is to identify all infected inmates so that they can be quarantined, then testing must be mandatory.[6] However, in Oregon, prison officials decided to use a health facility model of infection control and to implement universal HIV precautions rather than try to identify and quarantine infected inmates. One reason for this decision was that the average prison stay in Oregon is only 16.8 months (Oregon Department of Corrections, Statistical Report, PP30TC11, May, 1988). A policy that isolates HIV positive inmates while they are imprisoned does little to prepare either the prisoner or society for the near future when they are released.

Given these preconditions, the primary reason to test inmates in Oregon would be to inform them of the results, in hopes that this information would help them to implement risk reduction behavior. The data from this study provide insight into the kind of testing program that would most likely accomplish this goal.

The prevalence of HIV infection among prisoners entering the Oregon correctional system at the end of 1987 was 1.2 percent. While this estimate is relatively low compared to infection rates of 15 percent–20 percent reported in prison populations in high AIDS incidence areas,[3,7,8] it is probably more representative of that expected in most states. Oregon is nineteenth among states ranked by cumulative reported AIDS incidence rate.[8] To date, prisoner seroprevalence data have been reported from 20 states; in 17 of the states (85 percent), seroprevalence was less than 2 percent.[2]

In contrast to the low HIV seroprevalence, 63 percent of inmates entering Oregon corrections system were either HBcAb positive or admitted to IV drug use or male homosexuality, all indicators of potential risk for future HIV infection. The ratio of uninfected to infected at-risk inmates was 53:1.

The problem then is not that there are a lot of infected inmates that need to be identified. Rather, there are a lot of at-risk, as yet uninfected inmates that need to be convinced to change their behavior. To be effective, prevention programs must be specifically directed at this latter group.

To our knowledge, the influence of mandatory HIV testing on subsequent behavior has not been evaluated. It seems particularly unlikely, however, that forced testing would significantly change the conduct of those testing negative. In

contrast, multiple studies have documented that voluntary HIV testing and counseling can change behavior.[9–15] More importantly, this intervention has specifically been shown to cause the at-risk client who tests negative to initiate risk reduction behavior.[12–14] When most persons at risk are not yet infected, voluntary HIV prevention programs that emphasize counseling may be more effective than mandatory programs that emphasize testing.

Our study demonstrates that such a voluntary program can be successfully implemented in the prison setting. In Oregon, two-thirds of all inmates, including those at highest risk for HIV, sought HIV counseling and testing when given the opportunity.

In conclusion, we believe this study shows that an effective HIV intervention program for Oregon's prisoners should contain the following components: general AIDS education for all prisoners to raise their basic awareness of the disease; counseling at the prisoners request, especially for those who indicate they may be at risk; and HIV testing, offered only as voluntary component of this counseling, so that testing cannot occur without counseling, but counseling can occur without testing. Anonymous HIV testing was attractive to some inmates who declined confidential testing and when feasible should be considered as a testing option.

The Oregon Legislature has accepted these recommendations and approved the funding necessary to implement a comprehensive voluntary HIV counseling and testing program in Oregon prisons.

ACKNOWLEDGMENTS

The authors would like to thank Roberta Pfeiffer of the Oregon Public Health Laboratory for her work with the preparation of specimens, Loraine Good of CDC for her editorial contributions, and the health staff of the Oregon Corrections Department for their logistical support.

Task Force Report on Clinical Preventive Services

The US Preventive Services Task Force recently completed a five-year review of numerous clinical interventions and presented their recommendations to Dr. J. Michael McGinnis, deputy assistant secretary for health (disease prevention and health promotion). Their report, entitled *Guide to Clinical Preventive Services*, was unveiled May 2 during a news conference in Washington, DC.

The report is the work of a 20-member non-federal panel appointed in 1984 to develop age- and risk factor-specific recommendations for the delivery of preventive services in the clinical setting. The report addressed the effectiveness of over 100 clinical interventions for the prevention of 60 diseases. Its basic recommendation is that clinicians should tailor preventive examinations to the individual patient rather than routinely performing a battery of tests on patients which may be ineffective and could lead to inaccurate results.

The report recommends four types of interventions in the clinical setting: screenings, counseling, immunizations, and chemoprophylaxis. Of these, said Robert S. Lawrence, MD, who chaired the task force, counseling patients about behavior modification can be among the most effective forms of preventive, adding that ". . . the key to improved health and disease prevention often lies in lifestyle changes made by patients rather than in the broad testing or sophisticated medical procedures performed by health providers."

The all-volunteer task force was comprised of 14 physicians as well as specialists in dentistry, nursing, health services research, health education, health economics, and medical sociology. The report—Guide to Clinical Preventive Services—will be published by Williams and Wilkins of Baltimore, MD in late summer. For further information, contact the publisher at 1-800-638-0672.

Emergency Room Use and Primary Care Case Management: Evidence from Four Medicaid Demonstration Programs

ROBERT E. HURLEY, PHD, DEBORAH A. FREUND, PHD, AND CAPT. DONALD E. TAYLOR, USAF

Abstract: Claims-based utilization data collected in four Medicaid demonstration programs are used to examine the impact of primary care case management on patterns of reliance on the emergency room as a source of services. The experience of stratified random samples of AFDC (Aid to Families with Dependent Children) adults and children in the demonstration programs is compared with that of equivalent samples from comparison groups in traditional Medicaid programs. Data were analyzed in multivariate models controlling for person characteristics in a pre/post, demonstration/comparison design. Results indicated large reductions in the proportion of persons with at least one emergency room visit ranging from 27 to 37 per cent for children and 30 to 45 per cent for adults. Use levels for persons with at least one ER visit are less substantially affected. The findings suggest that gatekeeping designs can alter patterns of enrollee use with respect to the emergency room and some discussion of these implications is presented. (*Am J Public Health* 1989; 79:843–847.)

Introduction

Access to health care by low income Americans has been of considerable policy concern for the last two decades. Of special import has been the finding that poor individuals are less likely than persons of more substantial means to have a regular source of care. Thus, for a variety of institutional and economic reasons, these persons are more likely to use emergency rooms instead of private physicians for their basic medical care.

Primary care case management programs offer promise for reducing reliance on the emergency room as a regular source of primary care.[1] By channeling access to all medical services through a primary care provider, these programs make available other sources of care and provide constraints on the free access to the emergency room for non-emergency services. This two-pronged approach has been of special interest to state Medicaid agencies concerned about improving access to care and using program dollars more cost efficiently.[2,3]

A substantial base of research has been accumulated to demonstrate that the majority of services rendered in emergency rooms has been for non-urgent care[4–7] and that low income persons are disproportionate consumers of primary care in the emergency room.[8] These patterns of use have been attributed to the accessibility of the emergency room during non-traditional hours of operation; its relative proximity to care-seekers brought on by the maldistribution of primary care providers; or absence of alternative sources due to ability to pay.[8] For state Medicaid agencies this reliance on the emergency room has been shown to lead to higher costs.[9]

Complementing these findings is a large literature indicating that the availability of a regular source of care from alternative sites such as office-based physicians or health centers can be effective in diverting care from the less desirable emergency room.[10,11] In an era characterized by severe retrenchment in Medicaid programs, reductions in emergency room use might be expected to produce real savings without reductions in access, if the availability of alternative sources of care can be ensured.

In this study, we report results from four Medicaid demonstration programs that, among other goals, targeted emergency room use for reductions via primary care case management.

Methods

Study Settings

The Health Care Financing Administration (HCFA) approved eight demonstration programs in six states in 1982 that are referred to as the Nationwide Medicaid Competition Demonstrations.[12] These demonstration programs incorporated components of capitation, case management, and limitation on freedom of choice.[2] Four of these programs have been examined extensively in the HCFA-funded evaluation contract awarded in 1983.[13] The focus of the evaluation was on the impact of the programs on the utilization and cost experience of enrolled beneficiaries in each demonstration program in comparison with the experience of equivalent samples of non-enrollees.

We studied two county-based demonstration programs in California and state operated capitation programs in Kansas City, Missouri and the state of New Jersey.[12] All four of these programs used a gatekeeper (case manager) model in which eligible persons were enrolled with a participating individual physician or primary care organization. The gatekeeper was required to provide all primary care and to authorize referral care, including all inpatient and non-urgent emergency room use. Initially enrollees were permitted to select their case manager in each site but were limited to using their selected provider thereafter.

In all four programs, the state Medicaid agency paid the entities with which it contracted on a prepaid basis. The capitated rate differed for each public assistance aid category included in the demonstration. In California, the contractors were county-based, quasi-governmental authorities which in turn negotiated contracts with medical care providers within the demonstration county to provide primary care case management. The two California and the Missouri programs were mandatory for Medicaid eligible persons in the covered categories while the New Jersey demonstration was a voluntary enrollment program.

Several other differences existed among the four programs. The Santa Barbara (CA) program paid case managers on a capitated basis for primary care services while the

Monterey (CA) program continued to pay them on a fee-for-service basis plus a nominal monthly case manager's fee. Both of the California programs permitted some institutional providers to participate, i.e., health centers and hospital clinics, though the preponderance of case managers were individual physicians. Primary care providers in both California demonstrations were required to share financial risk with the intermediary organization, by participating in savings and losses resulting from specialist and emergency room use that was different from predicted levels. Case managers in New Jersey were paid on a capitated basis for primary care services similar to Santa Barbara.

The Missouri Medicaid program engaged five organizations and paid them on a capitated basis for covered services: two neighborhood health centers, two hospital outpatient clinics, and an IPA-model health maintenance organization.[14] Only in the IPA were enrollees assigned to a specific primary care case manager while in the remaining providers the organization was, in effect, the case manager. Missouri also permitted approximately 50 individual physicians to perform case management for their existing Medicaid patients. These physicians continued to be paid on a fee-for-service basis with a supplemental case management fee paid each month for each enrollee, similar to the arrangement in Monterey county in California.

Given the basic similarities in program designs with respect to prior authorizing non-urgent emergency room use, all of the programs were expected to effect reductions in levels of emergency room use by lowering the number of unnecessary visits in the emergency room and by increasing access to alternative sources of primary care. We hypothesized these reductions would be detected for both adult and children enrollees. Furthermore, reductions were expected to be detectable in both the probability that an enrollee would have at least one visit and in the mean number of visits for enrollees with at least one visit.[15]

Data Source

Person-level analysis files have been constructed from Medicaid eligibility and claims records for Medicaid beneficiaries residing in the demonstration counties and for equivalent samples residing in selected comparison counties in California and Missouri. Ventura County was chosen because of its similarities with and geographic proximity to both California demonstration counties. St. Louis was selected because it is the only other major metropolitan county in Missouri. Since enrollment in New Jersey was statewide and voluntary, we selected a comparison group of non-enrollees from persons who were never enrolled in the demonstration program. We drew random samples of approximately 3,000 adults and children stratified by eligibility category and age from eligibility files for the year prior to implementation and for the first full year of the demonstration programs. Cost and analytical considerations precluded us from selecting a panel design and we have used a pre/post non-equivalent comparison group design to analyze our two cross-sections of data.

In the pre- and post-periods for both sites, we used claims data collected in the Medicaid Management Information Systems of each state to construct data on emergency room use. In Missouri, the claims data were partially comprised of "pseudo-claims" submitted by the capitated plans who were responsible for paying emergency rooms directly for visits by their enrollees and then submitting a pseudo or no-pay claim to the Medicaid agency. In all other sites, emergency room visits were paid directly by the state Medicaid agency.

We developed an algorithm to transform claims files into visit (event) files.* An emergency room visit is defined as a medical event that occurred in the emergency department of a hospital. Medical events were created by accumulating all medical services provided to the same person on the same day into a single measure of use. Place of service is determined by the location codes on the claims received for the services accumulated into a particular event. An indicator of having had at least one emergency room visit and the count of visits for persons with at least one such visit were accumulated to the person level records built from the samples described above. We present results for the AFDC population only since this was the only eligible group for whom results were available from all four sites.

Analysis

For each person in each of the four demonstration-comparison contrasts, we collected information on age, sex, race (not available in California), total months of eligibility in the studied year, whether a person had insurance coverage beyond Medicaid (not available in Missouri), and whether the person had continuous eligibility through the study year; in addition to these personal characteristics, variables included presence in the demonstration or comparison group, and in the pre-year or demonstration year samples. Finally, a program effect variable was modeled as an interaction term of pre/demonstration year and demonstration/comparison county and coded as follows: 1 if in the demonstration county in the demonstration year and 0 otherwise. The multivariate approach is described in greater detail in the Appendix. Separate analyses were conducted for children and for adults.

In each of the four contrasting sites, we developed estimates of the effects of each of these independent variables on the probability of use and the volume of use for users employing logit and ordinary least squares regression, respectively. While probit is the preferred statistical application with probability of use,[15] we selected the less costly and more easily retransformed logit approach since it produces virtually identical results in this case.[16]

Results

Table 1 presents our estimates of the regression-adjusted proportion with at least one visit and the percentage change in this proportion from the pre- to the demonstration year for both the demonstration group enrollees and the comparison group enrollees for AFDC mothers and children separately.

There is close comparability between demonstration and comparison groups across all four contrasts in the year prior to the demonstrations with emergency room visits higher in the two urban Missouri counties and the New Jersey enrollee and non-enrolled groups than in the less urban California counties.

The change in proportion of Medicaid beneficiaries with a visit is relatively small from the pre-year to the first year of the demonstration for comparison group members in each contrast. However, substantial reductions are noted in all of the demonstration programs in the demonstration year. For children, these reductions range from 27.5 per cent in Santa Barbara to 36.7 per cent in New Jersey. For adults the reductions were even larger ranging from a low of 30.6 per

Demo-year	FY 84	FY 84	FY 85	CY 85

cent in Santa Barbara to 44 per cent in both Kansas City and New Jersey.

The analysis of program effects for persons with at least one visit found much weaker evidence of gatekeeping impact on emergency room users. Significant reductions were found for AFDC children in Monterey, Santa Barbara, and New Jersey but not in Missouri. Although reductions were detected for adult users in all of the demonstration sites, none of the interaction terms produced a p value less than .05. Because emergency room use is a relatively infrequent event, significant changes for users may be more difficult to detect with correspondingly smaller sample sizes.

Discussion

These results suggest the gatekeeping effects of primary care case management programs are strong and pervasive with respect to likelihood of an emergency room visit. Despite substantial variation in program designs, the effects were noted in each demonstration program for both children and adults. The findings should, however, be tempered by the fact that our cross-sectional design is unable to control for all potentially confounding factors that might influence the results.

While these findings confirm the expectations of the state and federal officials responsible for designing these demonstrations, the magnitudes of the effects are surprising for three reasons:

- Despite the gatekeeping design, case managers had broad discretion to authorize emergency room use and could choose to exercise this discretion either loosely or rigorously.
- Emergency rooms in some sites expressed great reluctance to deny care to on-site patients for whom authorization could not be obtained,[12] indicating direct gatekeeping effects would be attenuated in these sites.
- The results presented from each site are from the first year of demonstration program operation indicating that learning effects associated with greater comprehension of the implication of gatekeeping would have been limited during this period.

The sharp reductions in probability of a visit for adults and for children in the first year suggest that the gatekeeper concept was apparently reasonably well understood by enrollees. They may also suggest that the requirement of around-the-clock availability of the primary care case manager provided an accessible alternative to the emergency room. The data presented here do not permit us to attribute the reduction specifically to either or both of these program features and this issue is still under study in the demonstration evaluation. The fact that use for users was not so dramatically affected as probability of use suggests gatekeeping for individuals with a propensity to use the emergency room is less effective or perhaps less suitable.

Another interesting implication of the results presented here is the effectiveness of primary care case management in reducing emergency room use irrespective of the method by which the case manager is paid. For example, the fee-for-service Monterey program had gatekeeping effects similar to those found in Santa Barbara and New Jersey, which capitated primary care, and in Kansas City, which capitated nearly all covered services. This finding is especially notable given the notoriety achieved by Monterey with its subsequent dissolution in insolvency and its widespread characterization as a demonstration program failure.[17] There is also no apparent difference in effects on probability of a visit and use for users that is attributable to the method of case manager payment. Capitation does not appear to be any more effective in reducing use for users than does fee-for-service, as might be hypothesized.

The data presented here are silent on a critical question related to emergency room gatekeeping: is it non-urgent emergency room use that is being reduced in the demonstration programs? Because the program designs do not require prior authorization for bona fide emergencies, we may suspect that emergency room reductions would not be or, at least, need not be occurring for such conditions. Furthermore, the National Medical Care Utilization and Expenditure Survey (NMCUES) estimated that 85 per cent of emergency room visits are for non-life threatening reasons.[18] Thus, despite the large reductions attained in emergency room use in the demonstration programs, we may infer that levels of use in the programs still include a substantial amount of primary care.

In a detailed study of the Kansas City demonstration using data from a consumer survey,[19] we have attempted to

assess if remaining emergency care was "necessary" using both patient-assessed and clinical-based measures. We concluded that lower levels of use were associated with a higher proportion of remaining visits being clinically necessary. Unfortunately, the claims-based data employed here do not permit this analysis to achieve the same type of detail. However, other studies from related data bases indicate that access to and satisfaction with care for enrollees and nonenrollees were comparable in Missouri and California.[20] A quality of care study using outcome data has found no evidence to suggest adverse consequences associated with reductions in emergency room visits.[21]

It is notable that while emergency room use has been reduced, primary care visits in most sites did not increase correspondingly as might have been expected if substitution of such care were occurring. This finding may indicate an improvement in continuity of care fostered by formal enrollment with a responsible case manager. Other results from the evaluation have demonstrated that there are significant increases in the concentration of enrollees' care with their case managers.[22] If access to care has not been impeded and if quality of care has not changed, then these capitated demonstration programs appear to be capable of producing meaningful improvement in the continuity of care for beneficiaries, as well as real, although modest, cost savings for Medicaid agencies.

APPENDIX

Multivariate Approach Used in the Medicaid Competition Demonstrations Evaluation

Analysis of covariance techniques were used with dummy variable specifications of the time periods and demonstration versus comparison groups. The generic specification of the regression model is as follows:

$$Y = B0 + B1(DEMCOMP) + B2(PREPOST) + B3(PROGRAM) + BkX + U$$

where:

Y = specific dependent utilization measures under examination;

DEMCOMP = a dummy variable indicating if the observation came from the demonstration or comparison group (coded 1 if demonstration; 0 if otherwise);

PREPOST = a dummy variable indicating if the observation came from the pre- or post-(demonstration) year period (coded 1 if post-year; 0 if otherwise);

PROGRAM = a term defined as DEMCOMP × PREPOST used to indicate if observation came from demonstration group in the demonstration year (coded 1 if both DEMCOMP and PREPOST = 1; 0 if otherwise);

X = a vector of control variables, including demographic and eligibility characteristics;

U = the error term.

B0 and B1 to Bk constitute the intercept term and the regression coefficients being estimated that lead to the estimate of program effects.

The parameter estimates for DEMCOMP, PREPOST, and PROGRAM are summarized in the Appendix Table.

Appendix Table

		Site		Difference
		Comparison	Demonstration	(Demo–Comp)
Time Period	Pre	B0	B0+B1	B1
	Post	B0+B2	B0+B1+B2+B3	B1+B3
Difference (Post-Pre)		B2	B2+B3	B3

To generate the regression adjusted proportions with an emergency room visit shown in Table 1, predicted values for each site and year were produced controlling at the mean levels on the included control variables. Further detail on the analytical approach including the full regression results are available from the authors.

Determinants of Community-Based Coverage: Periodic Vitamin A Supplementation

IGNATIUS TARWOTJO, MSc, KEITH P. WEST, JR, DrPH, RD, LISA MELE, MS, SUKARNO NUR, MPH, HENNY NENDRAWATI, BSc, DANIEL KRAUSHAAR, DrPH, ROBERT L. TILDEN, DrPH, AND THE ACEH STUDY GROUP*

Abstract: Factors related to preschool child receipt of vitamin A during the first year of a semi-annual vitamin A capsule delivery program were investigated in 229 villages in Aceh, Indonesia. Coverage was higher in villages which were more rural and less economically developed. Highest performance was achieved by village distributors who represented the local status quo in this rural area (farmers, or non-farmers with minimum education) rather than more upwardly mobile, highly educated residents. Household or child-level characteristics were not associated with coverage. This information may be useful for planning direct service programs in the community. (*Am J Public Health* 1989; 79:847–849.)

Introduction

Vitamin A deficiency is the major cause of pediatric blindness in developing regions throughout the world.[1] Milder systemic vitamin A deficiency may also predispose children to greater risk of infectious morbidity[2] and mortality[3–5] and appears to be an important determinant of child growth.[6,7]

One major strategy for preventing vitamin A deficiency in the community is through periodic delivery of oral doses of vitamin A (usually 200,000 IU every four to six months) to preschool age children. Distribution can be carried out either as a special, single-purpose program or integrated into existing primary health care activities.[8] Presently, over 100 million oral doses of vitamin A are distributed annually, the bulk of which are provided as gelatin capsules by UNICEF.[9]

Community and distributor factors influencing capsule coverage are largely unknown. These characteristics were investigated during a semi-annual, large-dose vitamin A supplementation program in Indonesia from 1982–84.[10]

Methods

This evaluation formed part of a large community trial designed to assess the impact of vitamin A supplementation on childhood xerophthalmia, mortality, and growth in the north Sumatran Province of Aceh—population: 3.87 million; area: 55,390 sq. kilometers. The basic study design and findings on mortality have been reported.[4] Two-hundred-twenty-nine villages were randomly selected to receive the Indonesian Government's single-purpose vitamin A capsule distribution program operated through the provincial health service. Village distributors were identified based on village headmen recommendations and a minimum fluency in reading and writing the Indonesian language. Two days' training were given at local health centers concerning the purpose of vitamin A distribution, program organization, house-to-house visiting and oral dosing procedures, record keeping and reporting. Distributors were paid an honorarium equivalent to US $2.00 (1983) for each six-monthly distribution, per government guidelines. Normal supervision was strengthened by adding two study monitors who visited program villages and encouraged as complete coverage as possible.

Village, distributor, household, and child characteristics were assessed during a baseline survey by two field teams. Capsule distribution began within two months after the survey, and again six months later. Coverage, assessed one year after the baseline survey, was considered adequate if children received a vitamin A capsule at both capsule distribution cycles. Stratified continuous and discrete data were analyzed by the chi-squared test.[11] A multiple linear regression model was fit to data to examine the adjusted effects of selected factors on coverage.[12] Data were analyzed using SAS (SAS Institute, Cary, NC).

Results

Distributors selected by village leaders differed from heads of household in program villages (from which they were likely to have been drawn) (Table 1) with larger proportions being younger, female, and better educated (possibly due to the program's minimum literacy requirement).

More than half (54 per cent) of all program distributors achieved high, 30 per cent moderate, and 16 per cent low coverage of children at both distribution cycles (Table 2). Education was inversely related to distributor performance. Farming was related to higher coverage compared to non-farming occupations (mostly government workers, self-em-

ployed, and craftsmen). Cropland ownership was associated in a somewhat unexpected fashion to coverage: distributors who owned only a small amount (0 ha < X <½ ha) performed poorly compared to those who owned either ≥½ ha or no cropland at all. Other distributor characteristics such as age, sex, ownership (bicycle, motorcycle, or radio), or relationship to the village headman were unrelated to distributor performance (not shown).

Capsule coverage was weakly associated with the size of a village (number of houses), but inversely related to a cluster of village "development" factors. Strongest was the association with proximity to a major (district or subdistrict) road, with twice the proportion (60 per cent) of more distant villages (≥1 km) having high coverage vs those in closer proximity (<1 km, 30 per cent). Similar associations were noted with distances to other development landmarks such as local health centers, weekly markets, and elementary schools (not shown). Lower coverage villages were more likely to have at least one commercial shop.

Multivariate adjustment by least squares linear regression confirmed the weak influence of village size, the strong positive effect of a village's distance from a major road, and the strong, negative effect of a distributor owning a small amount of cropland on coverage (Table 3). The influences of distributor occupation and education were manifest through an interaction: more education plus a non-farming occupation was associated with markedly poorer coverage than any of the other three joint categories of occupation and education. Further stratified analyses showed that 60 per cent of farmers achieved high coverage (regardless of education) as well as 55 per cent of poorly educated (<6 yrs) non-farmers. In contrast, only 38 per cent of better educated (≥6 yrs) non-farmers achieved high coverage.

At the household level, none of the following were related to capsule coverage (after adjusting for distributor

TABLE 3—Adjusted Influence of Village and Distributor Characteristics on Coverage (2 cycles) by Multiple Linear Regression Analysis[a] (n = 189)

Parameter[b,c]	Slope	Std error
Intercept	72.73	5.56
Vill Size 30–59	−3.92	3.68
Vill Size ≥60	−2.65	5.80

Cropland none	1.14	3.97
Cropland <½ ha	−14.38	4.78
Occup non-farm	5.52	6.56
Educ > 6 yr	0.40	4.45
Occup * Educ	−18.00[d]	7.90

[a] $r^2 = 0.17$

[b] Reference categories are (in descending order): vill size <30, maj road <1 km, cropland ≥½ ha, occup farmer, educ ≤6 yr.

[c] The "village shop" variable (reported in Table 2) was not included in the regression analyses due to a large number of missing values (n = 42).

[d] Slope estimates effect on coverage of being a non-farmer with >6 yrs education.

performance level): head of household age, sex, education, or occupation; maternal age or education; household size, house construction or its proximity to the center of the village. Similarly, neither sex nor age of children was related to capsule receipt.

Discussion

Questions about community factors which may influence population-based programs are of generic importance for any supplementation, immunization, or other direct delivery health intervention. The Aceh study was a community trial, designed to evaluate the impact of vitamin A distribution on multiple parameters of child health and to identify factors related to coverage within the context of an optimal, single-purpose distribution program which still adhered to existing national guidelines.

Distributor characteristics in this study represented those of individuals freely chosen by village headmen who were given no other formal selection criteria other than a basic ability to read and write the Indonesian language. As selected, slightly more than half of all distributors achieved high coverage at both dosing cycles suggesting a tendency for community leaders, when given the opportunity, to select responsible residents to carry out distribution. This may have been due in part to a clear perception in the community at the outset concerning the program's potential benefits to children. High coverage, however, more closely corresponded to a local lower-middle than upper socioeconomic scale. Less economically developed, more rural villages, and distributors who were either farmers or nonfarmers with minimum education were associated with higher coverage, characteristics more closely aligned with the status quo in this predominantly agricultural economy. Those owning a small patch of cropland performed the poorest, an effect which appeared to be independent of factors measured in the study. Presumably these were distributors engaged in other (unassessed) non-farming means of support. Selection criteria for distributor positions may be more predictive of performance when they represent a balance between the formal skills required for the job (e.g., minimum literacy) and local norms which represent the stable, adult, working class in the population.

Analyses of household and individual child factors revealed no associations with coverage. While this may be

due partly to imprecision of survey-based interviewing, these data suggest that factors other than those measured influence the chances of children receiving vitamin A supplements.

The large dose program in Aceh controlled xerophthalmia,[13] improved growth,[6] and reduced mortality by 34 per cent in target-aged children.[4] Although dramatic, this impact may have been attenuated by the less than complete coverage that prevailed[5]: benefits may have been even greater had all targeted children received vitamin A. Increased attention toward identifying factors that can strengthen community-based programs is likely to lead to both increased effectiveness, efficiency, and sustainability of direct service delivery.

ACKNOWLEDGMENTS

The Aceh Study was supported under Cooperative Agreement No. DAN 0045 between the International Center for Epidemiologic and Preventive Ophthalmology, of the Wilmer Institute, the Johns Hopkins University, and the Office of Nutrition, Bureau for Science and Technology, United States Agency for International Development (USAID), Washington, DC with financial support from Task Force Sight and Life, P.T. Vicks, Ford Foundation, Helen Keller International, UNICEF, USAID/Jakarta, Mobil Oil Corporation, and the Asian Foundation for the Prevention of Blindness.

Learning Disabilities:
Proceedings of 1987 National Conference Available

The Proceedings of the 1987 National Conference on Learning Disabilities is now available from the National Institute of Child Health and Human Development (NICHHD). The 575-page book, available free of charge, provides extensive up-to-date information on what is known about learning disabilities, and also points out what is not known and makes recommendations for future research.

The conference, which was co-sponsored by the Interagency Committee on Learning Disabilities and the Foundation for Children with Learning Disabilities, focused on research findings in five areas: neurobiology of learning and memory; specific developmental disabilities of reading, writing, and mathematics; developmental language disorders; social skills deficits; and hyperactivity/attention deficit disorder. For each topic, the Committee commissioned an expert in the field to write a comprehensive review paper describing recent research related to the cause, diagnosis, treatment and prevention of learning disabilities as well as identifying gaps in knowledge and areas for further research. These documents are published in full in the proceedings, along with commentaries by expert discussants.

Members of the Interagency Committee on Learning Disabilities were drawn from a number of federal agencies, including: NICHHD, the National Institute of Neurological Disorders and Stroke, National Institute of Allergy and Infectious Diseases, National Eye Institute, National Institute of Environmental Health Sciences, and Division of Research Resources of the NIH; the Food and Drug Administration; National Institute of Mental Health; Centers for Disease Control; Environmental Protection Agency; Office of Human Development Services; and Department of Education. NICHHD Director Dr. Duane Alexander was conference chairman. Dr. James F. Kavanagh, Associate Director of NICHHD's Center for Research for Mothers and Children, was executive secretary of the Interagency Committee and co-editor of the proceedings.

To obtain a single free copy of the proceedings, write to NICHHD Publications, P.O. Box 29111, Washington, DC 20040.

Transmission of Enteric Disease Associated with Wastewater Irrigation: A Prospective Epidemiological Study

HILLEL I. SHUVAL, BSCE, MRH, YOCHANAN WAX, PHD, PEREZ YEKUTIEL, AND BADRI FATTAL, MPH, PHD

Abstract: We conducted a prospective epidemiological study of possible enteric disease transmission by aerosolized pathogens from sprinkler irrigation of partially treated wastewater in 20 kibbutzim (collective agricultural settlements) in Israel between March 1981 and February 1982. Medical data were collected from the patients' files and daily logs of physicians and nurses at each kibbutz clinic (total population 10,231). Episodes of enteric disease were similar in the kibbutzim most exposed to wastewater aerosols (11.6 per 100 person-year) and the kibbutzim not exposed to wastewater in any form (11.0 per 100 person-year). No excess of enteric disease was seen among wastewater contact workers or their families as compared with the unexposed. No negative health effects were detected in this study which involved a large population, including many young children, exposed to treated wastewater aerosols generated at distances of 300–600 m. (*Am J Public Health* 1989; 79:850–852.)

Introduction

Wastewater reuse through irrigation has been a declared a national policy in Israel for the past 30 years. About 250 wastewater irrigation projects currently operate, utilizing some 70 per cent of the wastewater flow of the country; the resulting aerosols expose thousands of farmers and their families who work or live near the irrigated agricultural fields. To see whether dispersed aerosolized pathogens from wastewater sprinkler irrigation systems increase enteric or other diseases, our group has carried out three epidemiological studies in kibbutzim (agricultural collective settlements).

The first study was based on the analysis of official reported cases of communicable disease drawn from the records of the Ministry of Health[1]; the second on an analysis of morbidity as recorded in existing clinic records in the communities under study.[2] The first study, which had a number of serious methodological limitations[3] suggested increases in salmonellosis, shigellosis, typhoid fever, and infectious hepatitis but the second study did not confirm those findings. Nevertheless, the second study found a significant excess of enteric diseases, mainly clinical gastroenteritis, in the 0–4 year old age group in wastewater irrigating kibbutzim during the summer irrigation months only, with no excess of enteric disease detected on an annual basis.

We therefore conducted the present prospective study in 20 agricultural settlements in Israel with a total population of 10,231. The study concerns both occupationally exposed workers and their children and spouses, and the general population residentially exposed to the aerosols formed by sprinkler irrigation with partially treated wastewater. The effluent was not used for the irrigation of directly consumable crops. The presumed routes of exposure to enteric pathogens were dispersion of aerosolized wastewater to nearby residential areas, direct contact with wastewater by irrigation workers and contact of wives and children with wastewater irrigation workers.

Sero-epidemiological studies on the same population groups conducted during the same period are reported elsewhere.[4–9]

Methods

The kibbutz is a voluntary collective community, mainly agricultural, responsible for all needs of members and their families, in which there is no private wealth. Geographic location, climatic factors, quality of water supply, and level of food hygiene vary but socioeconomic and educational levels are uniformly high. The Health Insurance Fund of the General Federation of Labor—Kupat Holim—maintains local health clinics in each kibbutz, according to Western medical standards, with services available to all kibbutz members and residents at no charge. There is a very high level of interpersonal contact between infants and children because the community provides common care from a very young age.

After collecting baseline data in some 100 kibbutzim, 20 were selected on a matched basis for inclusion in the study as representative of Israel kibbutzim in terms of size, location, crops, and population.

All of the wastewater effluent used for irrigation in the 20 kibbutzim was only partially treated—a 5 to 10-day detention period in stabilization ponds—and was generally of poor microbiological quality with coliform concentration of $10^4 - 10^5$/100 ml. The irrigation period of May–August was common to all kibbutzim.

Study Population

The morbidity analysis was based on 20 kibbutzim meeting quality control criteria. The study population (N=10,231) including kibbutz members, candidates for kibbutz membership, their children and parents. The 20 kibbutzim selected were divided into three categories: A) Higher Exposure (seven kibbutzim) wastewater sprinkler irrigation within 300–600 m of residential areas; B) Lower Exposure (six kibbutzim) with wastewater use, but no exposure to aerosols; C) No Exposure (seven kibbutzim) control group; no use of wastewater. The age distribution in the 20 kibbutzim was similar for different categories (see Table 1).

Morbidity Data

Patients' visits to each kibbutz clinic were recorded by nurses or physicians and disease outbreaks recorded by the project staff. The diagnosis or symptoms recorded for each clinic visit were coded according to the International Classification of Health Problems in Primary Care (ICHPPC-2) elaborated by the World Organization of National Associa-

TABLE 1—Age Distribution in the Study Population of 20 Kibbutzim by Categories (per cent of all ages)

Categories	Age Groups (years)					
	0–5	6–9	10–14	15–24	25–54	55+
Total	16	11	10	9	37	17
A	15	9	11	11	38	16
B	16	9	9	10	38	19
C	16	14	9	7	35	18

tions of General Practitioners and based on the WHO International Classification of Diseases (ICD), 9th Revision. Population estimates for denominator were obtained from the Kibbutz-Movement Statistical Department.

One episode for acute or subacute enteric condition refers to one or more visits to the clinic by the same patient over a certain period of time for the same symptoms or disease. A new episode was recorded when there was an interval of 20 days or more between two visits for the same symptoms and disease. The most common enteric diseases likely to be transmitted by wastewater were chosen for this study (Table 2).

Statistical Analysis

The permutation-randomization test[10] was used to assess the significance of differences in the kibbutz episode rates between categories. This test does not assume that the rates within each kibbutz category follow identical distribution patterns and is not sensitive to the presence of a few outlying kibbutzim within a category.

Results

The morbidity analysis was based on the total enteric conditions reported since the number of specific disease entities were too low to allow for analysis and 95 per cent were non-specific. As Table 3 shows, the overall rates of enteric conditions for all ages in the seven kibbutzim exposed to wastewater aerosols from nearby fields (high exposure) was similar to rates in the six kibbutzim with only occupational exposure to wastewater (lower exposure) and the seven unexposed control kibbutzim (no exposure), both during the year and the irrigation season (May–August).

Table 3 also shows the rates for the 0 to 5-year age group. There were no differences between the higher exposed and no exposure on an annual basis. The apparent excess in mean enteric diseases rates in residentially exposed kibbutzim (49.1/100 vs 36.6/100) during the irrigation period was not statistically significant by the permuation-randomization test (P-value = 0.22) and was due to the high rate in one exposed kibbutz. When that kibbutz was excluded the mean rate for

**Four months (May–August 1981) episodes N×3×100/p = rate/year

the high exposure group was reduced to 29.4/100, which is lower than the no exposure group.

No excess of enteric disease outbreaks was found in wastewater irrigating kibbutzim, neither was there any association between drinking water quality and morbidity. No excess of enteric disease was found among wastewater contact workers, their wives or children.

Potential confounding factors, including microbial quality of drinking water and irrigation water, occupation, geographical region, age, and sex were not found to be consistently related to enteric disease rates.

Discussion

In our studies, low levels of bacteria and viruses of wastewater origin have been detected at distances of 730 m downwind of wastewater irrigated fields.[11] Although aerosolized enteric pathogens certainly can cause infection and disease in susceptible individuals, these morbidity data indicate that this does not commonly occur in the exposed study population.

These results contradict those of our first retrospective study,[1] which suggested possible transmission of typhoid, salmonellosis, shigellosis, and infectious hepatitis. It is possible that inaccuracies in official published figures which were used for the analysis account for the different results.[3]

Wastewater irrigation workers, the most highly exposed group, may be protected by their high levels of immunity to a broad spectrum of common enteroviruses.[9] Similar findings have been reported among wastewater workers in the United States, where initial levels of herd immunity are lower.[12]

Susceptible infants and children would be the most likely to show ill effects, as our earlier retrospective study[2] suggested, but no clear effects were found in the current study. During the irrigation season, young children in one kibbutz exposed to wastewater aerosols had high enteric disease rates, but children in the other six exposed kibbutzim did not.

The morbidity data from the present study showed no excess of enteric disease in all ages or in the 0 to 5-year age group on a yearly basis in wastewater aerosol exposed communities as compared to the non-exposed control communities. This finding is identical to that of the second

retrospective study.[2] This congruence of results between two independent studies reinforces this key finding.

A possible limitation in the study is that the high level of person to person contact in the communal infant and children homes and the common dining rooms could mask infrequent occurrence of disease associated with wastewater sprinkler irrigation. A strength of the study is that it included many infants with low immunity exposed to wastewater aerosols of poor microbial quality at relatively close range. If enteric diseases can be transmitted by such exposure to a significant degree, it should have been detectable under the conditions of this study. However, the evidence provided by this study does not point to any significant health risk associated with exposure to treated wastewater aerosols generated at distances of some 300–600 m from residential areas.

ACKNOWLEDGMENTS

Although the research described in this paper was funded by the United States Environmental Protection Agency (USEPA) under Grant No. CR-806416 to the Hebrew University of Jerusalem (Project Officers: Walter Jakubowski and Dr. Elmer Akin), it has not been subjected to the Agency's peer and policy review, and does not necessarily reflect the views of the Agency and no official endorsement should be inferred.

NIMH Earmarks $4.5 Million in 1989 for Homeless Mentally Ill

A new federal effort to benefit the homeless mentally ill was announced recently by Lewis L. Judd, MD, director of the National Institute of Mental Health (NIMH). "Improving the care and treatment of mentally ill individuals who are homeless is among the most pressing public health needs facing this country, and one of the most important priorities of the Institute," Dr. Judd said.

NIMH has budgeted some $4.5 million in Fiscal Year 1989 to launch a new Institute-wide program of research grants and demonstration projects that focus on the homeless mentally ill. The program will obtain essential knowledge about this population, their needs, and the best strategies for their care and treatment. Approaches to rehabilitative and other services for the homeless mentally ill will be rigorously tested and evaluated in actual service settings. The Institute also created a new unit in the NIMH director's office that will spearhead efforts to improve services to the homeless mentally ill.

Studies have shown that 30–35 percent of homeless adults suffer from a severe mental illness such as schizophrenia or manic-depressive illness. Less is known about the extent of mental illness among homeless families with children, a growing subgroup among the homeless. NIMH has supported research to identify the mental health, housing, and other support needs of the homeless mentally ill, and has also funded research, demonstration projects, and technical assistance efforts focusing on homelessness and its relation to mental illness. The new initiative represents a major expansion of those efforts.

The newly created NIMH Office of Programs for the Homeless Mentally Ill, to be located at NIMH in the Parklawn Building, 5600 Fishers Lane, Rockville, MD 20857, will be directed by Irene S. Levine, PhD; Debra J. Rog, PhD, will be associate director.

Accidental Ingestions of Oral Prescription Drugs: A Multicenter Survey

BARBARA J. JACOBSON, AMY R. ROCK, MPH, MURRAY S. COHN, PHD, AND TOBY LITOVITZ, MD

Abstract: Accidental ingestion of oral prescription drugs by children under age five continues to be a public health problem. A telephone survey of 1,866 ingestion incidents reported to nine poison control centers was conducted in the spring of 1986. Accidental ingestion occurred most often with a two-year-old child (42 per cent) in their own home (82 per cent). Thirty-five per cent of the toxic drugs ingested at home belonged to someone other than the immediate family, most often a grandparent. Toxic drugs were more often out of their usual storage location and in non-child-resistant prescription packaging, a nonprescription container, or in no container. Twenty-two per cent of all child-resistant packages were non-functional. Overall, at least 61 per cent of all medications had no child-resistant barrier at the time of ingestion. Accessible storage locations such as the kitchen counter, table top, or top of a dresser or bedside table greatly increased the risk of accidental ingestion. These results suggest the need for effective child-resistant packaging that is easier for all adults to use. (*Am J Public Health* 1989; 79:853–856.)

Introduction

The US Consumer Product Safety Commission (CPSC) is responsible for protecting children under the age of five from serious personal injury and death under the authority of the Poison Prevention Packaging Act of 1970. Its 1974 regulations require child-resistant packaging for oral prescription drugs. Previous studies have established that child-resistant packaging has indeed played a role in reducing injuries and deaths due to accidental ingestions.[1–3] Nevertheless, childhood poisoning is often due to ingested medications.[4–6]

In 1986, there were 49,281 accidental ingestions of oral prescription drugs involving children under age five reported to the American Association of Poison Control Centers (AAPCC), National Data Collection System;[7] 131 involved life-threatening symptoms, disfigurement, or residual disability; and four resulted in death. These numbers underrepresent the actual number of ingestions because they do not include ingestions reported only to other health care professionals and facilities.

Even without serious injury or death, ingestion incidents cause obvious emotional trauma to the child and his/her family. Therefore, the CPSC conducted a retrospective study to characterize specific factors that contribute to accidental oral prescription drug ingestions involving children under five years of age.

Methods

The study was designed to provide descriptive data about 2 025 incidents (225 from each of nine poison centers) of oral prescription drug ingestions involving children under 5 years of age.

One poison center from each of the nine US Census regions was selected to administer the study questionnaire and report to the American Association of Poison Control Centers (AAPCC) National Data Collection System.*

Interviewers from each poison center, selected by the center director, were (with one exception) poison center specialists who normally handle incoming calls at the center; they were trained in case selection and uniform interviewing techniques.

The study began in February 1986 and continued until the target of at least 225 cases of suspected prescription drug ingestions had been recorded by each interviewer. Study cases were consecutively selected from all incoming calls on the basis that the accidental ingestion involved an oral prescription drug and a child under five years of age. Excluded were ingestion incidents involving veterinary drugs; prescription ointments and creams in tubes; eye drops and ear drops; and lotions for dermal application. Also excluded were incidents where an adult gave a child multiple doses or too large a dose of prescription medication.

Data about the child, the medication ingested, and the medical effects experienced by the child were routinely recorded on the report form.

The study questionnaire was completed during a follow-up telephone interview with the individual who initially called the poison center or another adult who was in the household or at the location at the time of the ingestion incident. If necessary, at least 10 attempts to reach a respondent were made, including two in the evening and two on the weekend. The interviewer made the first attempt to contact a respondent within two working days of the initial incoming call. The involvement of an oral prescription drug and a child under age five was verified at the beginning of the interview.

The questionnaire was designed to collect information about the child, the ingestion site, the intended user of the medication, identification of any packaging, and the specific location of the medication when the child found it. For incidents involving non-child-resistant packaging, respondents were asked whether a specific request was made at the pharmacy for a non-child-resistant package.

All respondents who still had the involved package were asked if they would be willing to mail it to us at CPSC. Respondents who agreed were sent a postage-paid, preaddressed mailing bag.

A questionnaire was recorded for each child and for each drug involved in an incident. For incidents involving more than one child and/or more than one drug, the data were weighted to a one child/one drug basis. Any resulting fractional results were rounded to the nearest whole number. The results are descriptive and are presented on a per child or per drug basis as appropriate.

Address reprint requests to Barbara J. Jacobson, US Consumer Product Safety Commission, Directorate for Health Sciences, Room 724, Washington, DC 20207. Ms. Rock and Dr. Cohn are also with US CPSC; Dr. Litovitz is with the National Capital Poison Center at Georgetown University Hospital, Washington, DC. This paper, submitted to the Journal May 18, 1987, was revised and accepted for publication October 4, 1988. This study, conducted at the expense of the US Government, is considered in the public domain.

Results

There were 1,953 ingestion incidents involving 2,015 children under age five and 1,982 drugs: 1,866 incidents involved one child and one drug, 60 incidents involved two children and one drug, 24 incidents involved one child and two drugs, two incidents involved one child and three drugs, and one incident involved two children and two drugs. All incidents involved at least one oral prescription drug.

The study incidents were approximately 4 per cent of the reported 49,281 oral prescription ingestions involving children under age five in 1986.

The 1,953 incidents are 92 per cent of the 2,128 eligible incidents reported to the centers; 175 incidents were not included: 63 incomplete questionnaires, 44 refusals, 29 no eligible respondent, 25 wrong number given, and 14 non-working numbers given.

Eighty-nine per cent of the respondents were the individual who initially reported the ingestion to the poison center, 87 per cent were the child's parent, most often his/her mother.

The child's household most frequently had four members with a total annual income of $20,000 to $50,000. Eighty-one per cent of the children involved were White.

The drug categories included:

- *Antimicrobials*, including 297 flavored liquid antibiotics prescribed for the child or his/her sibling, were the most frequently ingested drugs (Table 1).
- *Oral contraceptives*, most often prescribed for the child's mother.
- *Toxic drugs*, most frequently prescribed for the child's grandmother (38 per cent, n = 228) or mother (32 per cent, n = 192).

Overall, more males were involved (56 per cent) than females (44 per cent). The peak age was two years (42 per cent); few incidents involved children under age one. Two-year-olds ingested non-toxic drugs as frequently as toxic drugs (41 per cent vs 44 per cent). Children under age two ingested more toxic than non-toxic drugs (36 per cent vs 19 per cent); children over age two ingested more non-toxic than toxic drugs (37 per cent vs 23 per cent).

TABLE 1—Categories of Oral Prescription Drugs Ingested by 2015 Children under Age Five

Drug Categories	n = 1982 (%)
Non-toxic*	
Antimicrobials	516 (26)
Oral contraceptives	200 (10)
Hormones	87 (4)
Toxic**	
Analgesics	199 (10)
Cardiovascular drugs	174 (9)
Sedatives/hypnotics, antipsychotics	124 (6)
Asthma therapies	41 (2)
Anticonvulsants	33 (2)
Antidepressants	30 (2)
Other	
Electrolytes/minerals	124 (6)
Cough and cold preparations	104 (5)
Vitamins	90 (5)
Diuretics	50 (3)
Anticholinergics	38 (2)
Antihistamines	35 (2)
Gastrointestinal preparations	30 (2)
Muscle relaxants	19 (<1)
Miscellaneous	88 (4)

*Drugs rarely associated wtih adverse effects other than minor gastrointestinal symptoms, even when ingested in large amounts.

**Drugs commonly associated with severe systemic toxicity.

Site and Intended User

Eighty-two per cent (n = 1652) of all children were at home when the ingestion occurred. The intended user of the medication was most often the child's mother (27 per cent) followed by the child him/herself (22 per cent). Children that were not at home were most frequently at the home of a grandparent (60 per cent) or an aunt or uncle (14 per cent). Thirty-five per cent of the toxic drugs ingested in the child's own home belonged to someone not in the child's immediate family (Table 2), most frequently the child's grandparent.

More toxic than non-toxic drugs were ingested at locations outside the child's home (32 per cent vs 9 per cent).

Of the 2,015 children, 1,471 developed no symptoms, 247 were estimated to have a non-toxic exposure, and four exhibited unrelated symptoms; 231 children experienced minor symptoms, 18 experienced moderate symptoms usually requiring treatment, 37 were estimated to have a potentially toxic exposure, and seven experienced life-threatening symptoms. There were no deaths.

Over half of all drugs ingested were located in the kitchen/dining area (53 per cent). Liquid flavored antibiotics were the most frequently ingested preparation and the refrigerator was the most common location (13 per cent). Twelve per cent of the ingested drugs were on the kitchen counter and 7 per cent were on the table.

The toxic drugs were found in the bedroom almost as often as in the kitchen (31 vs 38 per cent). In the bedroom, medicine was most frequently stored on top of the dresser or bedside table.

Only 2 per cent of all drugs were stored in a bathroom medicine cabinet. Ten per cent were stored in a purse (30 per cent of all birth control pills).

Overall, the drugs were stored in their usual location only 53 per cent of the time. In fact, the toxic drugs were more often out of their usual location (65 per cent of the time) and were frequently on the floor or a low, open storage place.

Table 3 shows that more toxic than non-toxic drugs were in non-child-resistant prescription packaging (18 vs 7 per cent).

Seventy-five per cent (n = 235) of all non-child-resistant packages were reportedly dispensed by the pharmacist without a request from the purchaser or the prescribing physician.

Most of non-child-resistant packages (76 per cent) had been dispensed to parents of a child under age five.

TABLE 2—Site Where Accidental Ingestion Occurred and Intended User of the Most Potentially Toxic and Non-toxic Drugs

Site and Intended User	Toxic Drugs n = 601 %	Non-toxic Drugs n = 803 %
Child's Home	68	91
Immediate Family*	(41)	(82)
Other Live-ins	(14)	(4)
Visitor	(10)	(4)
Intended User Unknown	(3)	(1)
Some Place Else	32	9
Immediate Family*	(2)	(3)
Not Immediate Family	(30)	(6)
Intended User Unknown	(<1)	(0)

*Includes child, siblings, and parents.

TABLE 3—Type of Package Drug Was Stored In at the Time of Ingestion

Variables	Toxic n = 601 %	Non-toxic n = 803 %	All Drugs n = 1982 %
Child-resistant*	29	47	39
Non-child-resistant	70	27	50
Child-resistant package (closure left off or loose)	(6)	(9)	(9)
Non–child-resistant package	(18)	(7)	(16)
No container (loose pills)	(29)	(9)	(17)
Transferred to another container	(17)	(2)	(8)
Unit dose (oral contraceptives)**	0	25	10
Unknown	1	1	<1

*Includes child-resistant unit dose packaging.
**Excluded from child-resistant packaging requirement.

We received 382 of the requested prescription containers, 31 per cent of the 1,228 reportedly still available. Based on the opening and closing forces measured on mechanical testing equipment, 200 of the 306 (65 per cent) child-resistant packages received were not functioning within the normal force range for their specific design type. If the 65 per cent non-functioning packages received were extrapolated to all child-resistant containers (excluding unit-dose), the percentage of medications with no child-resistant barrier could be higher than 70 per cent.

The majority of the continuous threaded closures that were not functioning had been affected by the sticky liquid antibiotic in the package. Closures on the lug containers were non-functional due to wear associated with use.

Diseussion

This study had several limitations that may have biased the results:

- These data refer only to telephone calls to poison centers. We made no effort to gather data about ingestions reported only to other sources. Such ingestions could represent some of the most potentially toxic exposures that required immediate treatment in hospital emergency rooms.
- Our attempt to validate the package identification and measure function was incomplete because only 31 per cent of the prescription packages were sent to us. Some of the packages were no longer available at the time of the interview, which contributed to the low response rate. There is no reason, however, to suspect that the package identification is incorrect because those packages received did confirm the identification. Results on function are incomplete but do indicate the need for further evaluation of prescription packages.
- The reliability of responses to sensitive questions was not documented. For example, child-resistant closures that were left off or loose, drugs transferred out of their original prescription container, and drugs out of their usual storage place may be underreported because the truth involves an admission that carelessness contributed to the accidental ingestion.

A pharmacist who dispenses non-child-resistant packaging without a specific request from the consumer or his/her physician violates the provisions of the Poison Prevention Packaging Act. Respondents who were not the intended user of the ingested drug reported that a child-resistant package had been requested more frequently than respondents who were the intended user of the drug. This discrepancy may be related to the sensitivity of the question. Therefore, the results cannot be used to reflect pharmacist dispensing practices.

Other studies have shown that the personality and age-specific behavior characteristics of young children are important risk factors in accidental poisoning.[8,9] Children two to three years old were shown to be at greatest risk, confirming the results of several epidemiological studies.[4,6] The results of this study consistently showed that a lack of an effective child-resistant packaging barrier contributes to accidental ingestions of oral prescription medications. The accessible kitchen storage location identified is well documented in other studies and increases the risk of ingestion.[10–12] Storage on the kitchen counter, table top, or top of a dresser or bedside table suggests that the medication was being stored where it was convenient for the user to take. Results of a previous study found that the majority of ingested products were in use within 24 hours before the accident.[13]

A grandparent's home as an important risk factor has been identified in other studies as well.[14,15] Our results indicate that a grandparent's medication presents increased risks due to toxicity and the likelihood that the medicine will have no child-resistant barrier. A previous prospective study of poisonings that occurred away from home concluded that the products involved, most frequently drugs, were more potentially toxic and that these environments were seldom adequately prepared to handle toxic exposures.[16]

As the elderly population continues to expand and age, increased attention must be directed to educate these individuals about the risk of ingestion from their oral prescription drugs.

It is clear that packaging manufacturers have a responsibility to produce effective child-resistant prescription containers that are easier for adults of all ages to use.

Additionally, some practical method of safe storage is needed for drugs, particularly while they are in use.

Pharmacists, as well as dispensing physicians, have a key educational role to play when dispensing prescriptions, especially toxic drugs dispensed in non-child-resistant packaging.

ACKNOWLEDGMENTS

The study was conducted by the American Association of Poison Control Centers (AAPCC) under contract to the US Consumer Product Safety Commission. Telephone interviews were conducted by nine AAPCC poison control centers representing the US Census Regions; individual centers are identified in a footnote to the text.

The authors thank Angela M. DiVincenzo, PhD, Heidi Hartmann, Rodney Jenkins, RPh, Rita Mvros, RN, Sven Normann, PharmD, Judith A. Parrott, RN, Barbara Schmitz, RN, Maureen Stoen, RN, and Judith Woodard-Jenkins, RN, for their professionalism in conducting the interviews. The authors also thank Ms. Deborah Lockett for the hours of data entry. The views expressed are those of the authors and do not necessarily reflect the views of the US Consumer Product Safety Commission.

A summary of the results of this study was presented at the annual scientific meeting of the American Association of Poison Control Centers, American Academy of Clinical Toxicology, American Board of Medical Toxicology, and Canadian Association of Poison Control Centers, Sante Fe, New Mexico, September 25–30, 1986.

Congressional Task Force on Tobacco and Health

A new Congressional Task Force on Tobacco and Health—comprised initially of a bipartisan group of 35 members of the US House of Representatives—was announced in early May to focus congressional attention on the growing public policy issues associated with tobacco use.

Co-chairs of the task force are Rep. Richard J. Durbin (D-IL) who originated the 1987 law banning smoking on commercial airline flights of two hours or less duration, and Rep. Bob Whittaker (R-KS), sponsor of legislation to prohibit the sale of tobacco to minors and further regulate the sale and promotion of tobacco products. Among the other members are Reps. Henry Waxman (D-CA), chair of the House Energy and Commerce Subcommittee on Health, and Fortney Pete Stark (D-CA), chair of the House Ways and Means Subcommittee on Health.

Reps. Durbin and Whittaker said that the task force evolved as a result of the Conference on Tobacco Use in America, held last January at the M. D. Anderson Cancer Center in Houston, Texas. That conference brought together physicians, public health officials, and members of Congress specifically to address tobacco-related health issues. A comprehensive strategy for reducing tobacco use in America, drafted as a result of that conference, is to be announced by the task force. The stated purposes of the Task Force on Tobacco and Health are to:

- Educate Members of Congress and the public on tobacco use and its health effects;
- Build coalitions with other congressional organizations and public groups interested in tobacco use and tobacco-related health issues;
- Develop and coordinate strategies for advancing tobacco-related health legislation; and
- Assist Members of Congress in addressing the problems associated with tobacco use.

Individual members of the task force have sponsored a wide variety of bills aimed at helping to implement the goal of a smoke-free society by the year 2000. Those bills include: expansion of smoke-free zones in public buildings and transit systems; limitations on tobacco advertising; strengthening the warnings on cigarette labels; and raising the federal excise tax on cigarettes.

The Power of Policy: The Relationship of Smoking Policy to Adolescent Smoking

Mary Ann Pentz, PhD, Bonnie R. Brannon, EdD, Ventura L. Charlin, PhD, Edith J. Barrett, PhD, David P. MacKinnon, PhD, and Brian R. Flay, DPhil

Abstract: This study examined the effects of smoking policy on 4,807 adolescents in 23 schools over a two-county area in California. Amounts and prevalence rates of adolescent smoking were measured with a self-report survey and a biochemical measure; school smoking policy was measured with two independent surveys of school staff. Policy effects were evaluated with multiple and logistic regression analyses controlling for school-level socioeconomic status and environmental support for teaching and administration. Of the 23 schools, 100 percent had a formal written and regularly enforced policy component restricting student smoking on school grounds, 94 percent restricted students leaving school grounds, 65 percent restricted smoking near school grounds, and 57 percent had a smoking prevention education plan. Schools with policies having all four versus less than four components, high versus low emphasis on prevention, and a low versus high emphasis on cessation reported lower amounts of smoking in the last week and in the last 24 hours. Punitive consequences of policy violation had no effect. Results were compared to school staff observations of adolescent smoking, and school archival records of student smoking violations in the last year. Results suggest that school smoking policy is associated with decreased amounts of smoking in adolescents. (*Am J Public Health* 1989; 79:857–862.)

Introduction

Despite widespread knowledge of the health risks of cigarette smoking, 26.5 percent of adults and 18.7 percent of graduating high school seniors in the United States continue to smoke daily.[1,2] Fortunately, among adults, the prevalence of smoking and the associated rates of chronic disease mortality rates have declined steadily in the last 20 years.[1,3] However, among adolescents, smoking has decreased only 1.6 percent in the last five years.[4]

The effectiveness of school-based educational programs for preventing early adolescent smoking has been well documented.[5,6] Nevertheless, additional prevention strategies may be required to produce long-term changes in adolescent smoking behavior.

Over 90 percent of adult smokers who quit smoking do so on their own.[3,7–9] This percentage suggests that the steady decline in adult smoking prevalence rates may be at least partially attributable to efforts that have been aimed at motivating smokers to quit, such as anti-smoking mass media campaigns, increased taxation of cigarettes, public smoking education, and regulatory policies that restrict smoking in the workplace or public settings.[10–15]

No studies have yet evaluated the effectiveness of policy in reducing adolescent smoking. A logical approach would be to evaluate the effects of school smoking policy on adolescents, controlling for school-level socioeconomic status (SES), support for teaching and administration, and variables differentiating components of policy that relate to educational programming for smoking prevention from components that relate to regulation of smoking.[16,17] We undertook such a study.

Methods

Subjects

Subjects included 4,807 seventh grade students, 104 teachers, 21 principals, and 23 school clerks from 23 middle/junior high schools in Los Angeles and San Diego counties. The 23 schools represented all of the middle/junior high schools from three large school districts that are participating in a five-year trial of the effects of varied smoking education programs on prevention of adolescent smoking.[18] The average grade size per school was 213, with a student population characterized as high minority and low socioeconomic status (20 percent White, 27 percent Black, 44 percent Hispanic; 23 percent receiving free lunch as part of the federal Aid to Families with Dependent Children (AFDC) program). The population was 49 percent female.

Informed consent was required of both student and parent. Of the 6,101 students enrolled in seventh grade at the time of the study, 319 declined to participate and 975 were absent, resulting in a response rate of 79 percent. Of the school staff solicited for participation, 100 percent of teachers, 91.3 percent of principals, and 100 percent of school clerks responded and participated in assessment. Two principals (8.7 percent) who initially agreed to participate were unavailable during the data collection period and, consequently, were not assessed.

Policy

The California State Education Code bans all student smoking on school grounds in middle and junior high schools. At the initiation of this study in 1986, the policy had been in effect for an average of 34 years in the participating middle and junior high schools, and students had been exposed to the policy for an average of 13 months.

Measures

Sources of data included school archival records, a student self-report survey and biochemical measure of smoking, and surveys of teachers, principals, and school clerks.[19] (See Appendix for details of specific items analyzed for this study.)

Students completed a 109-item questionnaire measuring amount (number of cigarettes smoked) and prevalence rates (percent of smokers) of cigarette smoking in lifetime, last

week, and last 24 hours; related attitudes and behaviors; and demographic characteristics (gender, race/ethnicity, socioeconomic status).[20] During questionnaire administration, students also provided an expired air sample for carbon monoxide analysis of smoking, and were informed of the use of the sample as a test for smoking.[21,22]

The science and health education teachers and the principal of each school independently completed a 96-item questionnaire about staff and student smoking policies, including restriction of smoking on and near school grounds, a closed campus limiting opportunities for smoking off school grounds, and a formal educational plan for smoking prevention.[16,23] Staff awareness, perceived effectiveness of policy, and observations of staff and student smoking were also assessed. Environmental support for teaching and administration was measured using a modified form of the Moos Classroom Environment Scale, which was originally designed to assess supportive teaching environment in the classroom as it relates to student academic and social behavior.[24]

School clerks were interviewed with a 21-item survey which measured the extent to which smoking was allowed on school grounds, the length of years policy had been in effect, level of enforcement of policy, change in the number of smoking violations in the school in the last year, consequences of policy violation, and emphasis of the policy on punishment, prevention, and cessation.

Statistical Analysis

Separate t-tests were conducted to determine the equivalence of principal and teacher responses for pooling these groups in analyses. Principals and teachers did not differ in their reports of smoking levels of students or staff, or existence of policy or smoking prevention programs (none of the schools had smoking prevention programs). Within-school internal consistency of responses was high (calculated as a Cronbach alpha of all items across respondents within each school, average alpha = .83, ranging from .50–.99 for each school). Thus, principal and teacher ratings were averaged to produce one rating for each item for each school. For four schools in which the principal survey was incomplete, the rating for each item for that school was based on the average rating by the four to five teacher respondents.

Multiple linear and logistic regression analyses were conducted on each adolescent smoking item (amount and prevalence), with each policy variable (comprehensiveness, prevention emphasis, cessation emphasis, punishment emphasis) entered as an independent variable, and school-level socioeconomic status and school environmental support entered as covariates. To increase test validity, staff awareness and perceived effectiveness of policy were additionally controlled for in analyses of the effect of number of policy components. Separate t-tests were also conducted to determine whether individual policy components had a significant effect on smoking. The SAS software program was used for all analyses (GLM ANOVA for linear regression; CATMOD for logistic regression.[25] Analyses were conducted using school as the unit by aggregating individual respondents' data by school, and then merging the three data sets by a three-digit school identification code.

Results

Schools varied widely in the number and combination of policy components related to regulation of smoking (no smoking on school grounds, near school grounds, and closed campus), but were about evenly divided on the component related to smoking education (smoking prevention education plan). Characteristics of schools with and without a smoking prevention education plan were similar (Table 1). The groups did not differ significantly on any of the characteristics.

Averaged across all schools, 5.1 percent of adolescents reported having smoked in the last week, and 2 percent in the last 24 hours. Smokers averaged 7.1 cigarettes in the last week, and 2.3 cigarettes in the last 24 hours.

In a separate sub-study conducted under more controlled field test conditions, number of cigarettes smoked in the last 24 hours was assessed on a random sample of the same students one year later (n = 2,500) and correlated with a double expired air measurement following procedures by Biglan, *et al.*[21] The correlation of self-reported smoking with parts per million concentrations of carbon monoxide averaged r = .41, consistent with the average correlation of .35 reported by other researchers for similar age/grade groups.[22]

Effect of Policy on Smoking

As expected, all of the 23 schools had a formal rule banning smoking on school grounds; 22 (94 percent) also had a closed campus. However, only 65 percent had a rule banning smoking near school grounds, and 57 percent had a formal health education plan for smoking prevention programming, although none of the schools had implemented smoking prevention education at the time of this study. All of the school clerks reported that smoking policy was enforced "very regularly."

Table 2 shows the relation of policy to adolescent smoking, dichotomizing schools into two groups formed by the median split of each variable, for ease of illustration. Schools with all four policy components had lower smoking prevalence rates and lower mean amounts of smoking per smoker in the last week and in previous 24 hours than schools with less than four components. When schools with all four components were compared to schools with three or two components, differences in amount of smoking were more pronounced (see Figure 1). Regression analyses—using all four policy components and controlling for socioeconomic status, school environmental support, and staff awareness

TABLE 1—Characteristics of Schools with and without a Smoking Prevention Education Plan in Smoking Policy

Characteristics	Without Smoking Prevention Education Plan (n = 10)	With Smoking Prevention Education Plan (n = 13)

Based on N = 23 schools, school as unit of analysis. Means are adjusted for SES and school environmental support for teaching and administration, for the policy component variable, means are also adjusted for staff awareness and perceived effectiveness of policy.
†CI = Confidence Intervals

and perceived effectiveness of policy—indicated that number of policy components was related to lower amounts of adolescent smoking. Prevalence rates of smoking and smoking violations reported by school clerks were less strongly related to number of policy components.

Effect of Policy Emphasis

When policy emphasis variables were regressed on each smoking variable, controlling for socioeconomic status and school environmental support, results indicated that a high emphasis on prevention and a low emphasis on cessation were associated with lower amounts of smoking in the last week and 24 hours (see Table 2 and Figure 2); results were similar for smoking in the last week and the last 24 hours. Schools with a high emphasis on prevention also had lower weekly smoking prevalence rates and decreased school smoking violations in the last year. When prevention and cessation emphasis variables were entered simultaneously into regression analyses, both had an impact on amount and prevalence rates of smoking. However, punishment and severity of consequences for violation of smoking (number of consequences) had no effect. In all analyses, higher SES was marginally related to lower amounts of smoking.[*]

In general, the emphasis of policy on assisting (prevention and cessation) versus punishing students was significantly related to lower amounts of adolescent smoking and, less consistently, to lower smoking prevalence rates.

Discussion

Results of the study indicate that the number of components in school smoking policy (presumably representative of policy comprehensiveness) has a marginal effect on adolescent smoking, and the use of punitive measures to regulate smoking has no effect. On the other hand, the relative emphasis of policy on educating adolescents to stop smoking, and particularly to prevent smoking, rather than regulating smoking by punishment, is significantly related to lower recent smoking. More consistent effects were obtained on amounts of smoking rather than on prevalence rates, suggesting that current smoking policies for youth may work somewhat better for decreasing levels of smoking rather than for deterring smoking altogether or promoting cessation. Results do not appear to be confounded by any historical differences among schools in smoking risk or need for smoking cessation, as evidenced by the lack of difference among schools in school demographic characteristics, lifetime smoking prevalence rates of students, and staff smoking rates.

Our results are consistent with other recent cross-sectional studies of the relation of public or worksite no-smoking policy to smoking in adults, which suggest that policy may decrease cigarette consumption in settings affected by the policy, but not prevalence rates.[26–29] However, none of these studies is directly comparable to the present study, since each was based on a single policy with no differentiation of components or control for socioeconomic and environmental support variables; subsampling was used, with lower response rates; and policy effect was evaluated on an indirect or a single measure of smoking.

Adolescents may be more likely to comply with a smoking policy that is supportive and positive in focus. Such an interpretation is consistent with the findings of recent school-based smoking prevention studies that have shown positive skill-building prevention programs to be more effective in preventing or delaying the onset of smoking than programs focused on negative physiological consequences of smoking.[6] Also noteworthy is the finding that although all schools complied with the California state law banning smoking on school grounds, schools varied widely in representation of other policy components, staff awareness of policy, and consequences of policy violation. Perhaps most

surprising was the finding that none of the schools had implemented a smoking prevention program, despite reports that 57 percent had a formal educational plan for smoking prevention. Simply having a formal statement of policy is not likely to impact on adolescent smoking—the policy should emphasize smoking prevention and be actively implemented.

The findings of this study must be evaluated in the context of design limitations of policy studies. Although a longitudinal relationship between policy and smoking is assumed, since the smoking policies had been in effect in schools an average of 34 years and adolescents had been exposed to these policies in middle school an average of 13 months before smoking was measured, the study is cross-sectional. An experimental design of longitudinal policy effect would require random assignment of schools or other units to policy or no-policy conditions, after which policy would be initiated, and baseline to multiple follow-up changes would be evaluated.

The other design limitations relate to assessment. The results were based on analysis of self-report data. It is always possible that social desirability or recall biases affected the validity of the findings.[30] However, most studies on smoking prevention and cessation have shown that self-report data are highly valid and reliable, particularly when collected in conjunction with a biochemical measure.[19,21,22] Another limitation in assessment was the inability to differentiate smoking in and around the school setting and during school hours, from smoking in other settings and after school. Several worksite studies have suggested that smoking policy may work by delaying smoking until after hours or in other settings not affected by policy, rather than by actually changing smoking levels.[27–29,31] Although mean amount of smoking included smoking in all settings and times, it is still possible that the school policy effect is limited to reducing smoking only in and around the school.

In summary, this study suggests that smoking policy can have an effect on reducing amount of smoking by adolescents and, to a lesser extent, on smoking prevalence rates. Questions remain concerning the extent to which the effect of policy may interact with the effect of a smoking intervention in schools that are implementing both. For example, if the decreased amount of smoking in schools with a prevention-oriented smoking policy represents a conscious effort by smokers to cut down their smoking in preparation to quit, could this effort be expedited by a prevention program that is implemented in the school, or by a cessation program? In addition, little is known about the cumulative effect of multi-component smoking policies that are implemented simultaneously across several settings, e.g., a community smoking ordinance, a school smoking policy, and informal home rules about smoking.

APPENDIX A

Description of Items Analyzed for This Study

Variable	Source	No. of Items	Characteristics
Smoking			
Amount	Student questionnaire	2	No. of cigarettes smoked in last week, last 24 hours; continuous scale; high internal consistency, test-retest reliability.[19]
Prevalence Rate	Student questionnaire	3	0 = no smoking, 1 = any smoking in lifetime,† last week, last 24 hours, dichotomized from amount variables and aggregated to % of smokers in the school.
Current Staff†	Staff questionnaire	1	Continuous; estimated as % of staff currently smoking.
Observed Student‡	Staff questionnaire	1	Continuous; estimated as % of students observed smoking.
Smoking Violations‡	Clerk phone survey	1	Rated as change in last year, 1 = increased, 2 = decreased, 3 = stayed the same.
Expired Air (CO)‡	Student CO measure	1	Continuous, parts per million CO analyzed at 1 year follow-up.
Policy			
No. of Components (comprehensiveness)	Staff questionnaire	4	0 = no, 1 = yes for presence of formal (written and posted) rule about no smoking on school grounds, near school grounds, closed campus policy, formal health education plan for smoking prevention programming, summed to score 0–4; based on categories of school policy.[16,23]
Policy Emphasis	Clerk phone survey	3	1 = none, 4 = a lot for prevention, cessation, punishment.
Policy Enforcement‡	Clerk phone survey	1	1 = not at all, 4 = very regularly.
Time in Effect‡	Clerk phone survey	1	No. of years, months.
Consequences for Violation‡	Clerk phone survey	1	7 categories increasing in severity, re-scaled to 1 = detention, 2 = detention + other.
Policy on School Grounds‡	Clerk phone survey	1	0 = no, 1 = yes.
Staff Policy Awareness	Staff questionnaire	1	1 = low, 3 = high
Perceived Policy Effectiveness	Staff questionnaire	1	1 = low, 3 = high
Demographics			
Gender†	School archival records	1	% females in the school.
Race/ethnicity†	School archival records	2	5 categories re-scaled to % minority, % English as second language.
Socioeconomic Status (SES)	School archival records‡	1	% Aid to Families with Dependent Children.
	Student questionnaire	1	Father's occupation re-coded to 0 = no, 1 = professional occupation, aggregated to % in the school; high predictive validity for smoking.[20]
	Staff questionnaire‡	2	Community SES (1 = mostly professional occupation, 4 = mostly unskilled labor); summed across 2 items on school district and community SES, and standardized.
Student Achievement†	School archival records	3	% California Achievement Profile scores summed and averaged by school.
School Support	Staff questionnaire	20	1 = strongly agree, 4 = strongly disagree, summed and standardized; high validity and reliability for measuring supportive school environment.[24]

†Used for background descriptive information.
‡Used for comparison with other measures.

Treatment of Destructive Behaviors is Focus of NIH Consensus Conference

A Consensus Development Conference on Treatment of Destructive Behaviors in Persons with Developmental Disabilities will be held in Masur Auditorium at the Clinical Center, National Institutes of Health, Bethesda, Maryland, September 11–13, 1989. This open forum will focus on the various treatments and approaches used to modify or eliminate destructive behaviors in persons with developmental disabilities. The forum will address the following questions:

- What are the nature, extent, and consequences of destructive behaviors in persons with developmental disabilities?
- What are the approaches to prevent, treat, and manage these behaviors?
- What is the evidence that these approaches, alone or in combination, eliminate or reduce destructive behaviors?
- What are the risks and benefits associated with the use of these approaches for the individual, family, and community?
- Based on the answers to the above questions, and taking into account a) the behavior; b) the diagnosis and functional level of the individual; c) possible effects on the individual, family, and community; d) the treatment setting; and e) other factors, what recommendations can be made at present regarding the use of the different approaches?
- What research is needed on approaches for preventing, treating, and managing destructive behaviors in persons with developmental disabilities?

Sponsored by the National Institute of Child Health and Human Development of NIH, the National Institute of Mental Health of the Alcohol and Drug Abuse and Mental Health Administration, the Bureau of Maternal and Child Health of the Health Resources and Services Administration, and by the NIH Office of Medical Applications of Research, this NIH Consensus Development Conference will bring together biomedical investigators, practicing physicians, consumers, and representatives of public interest groups to provide a scientific assessment of drugs, devices, and procedures and to evaluate their safety and effectiveness.

On the first two days, experts will present current scientific thinking about the diagnosis, management, and prevention of destructive behaviors in persons with developmental disabilities, and concerned voluntary organizations will be invited to make statements. On the third day, after considering the scientific evidence, the consensus panel will present its draft report and invite comments from the audience. Dr. R. Rodney Howell, Professor and Chairman, Department of Pediatrics at the University of Miami School of Medicine, will chair the panel.

Containing Mental Health Treatment Costs through Program Design: A Massachusetts Study

BARBARA DICKEY, PHD, PAUL R. BINNER, PHD, STEPHEN LEFF, PHD, MARY K. UYEDA, MARK J. SCHLESINGER, PHD, AND JON E. GUDEMAN, MD

Abstract: A single site pre-post study of seriously mentally ill patients treated in a public mental health system shows that annual treatment costs can be substantially reduced with the use of day hospital treatment. Two cohorts of psychiatric patients—282 consecutive admissions to a traditional public inpatient unit in 1980, and 340 consecutive admissions to a combination of inpatient and day hospital care in 1984—were followed 12 months after admission. The substitution of the day hospital is made possible because the facility provided a dormitory residence for those who could not go home at night. Cost savings per hospital episode are about 31 per cent when the additional costs of day hospital and residence are considered. Cost shifting from inpatient to residential sites is noted, but overall mean annual costs, when all other treatment (including additional admissions), residential and family costs were included, are reduced. Readmission rates did not rise. The generalizability of the findings is limited to public mental health centers and state hospitals. (*Am J Public Health* 1989; 79:863–867.)

Introduction

After almost a decade of cost increases that have outstripped inflation, cost containment remains a primary concern of health policymakers. Cost reductions, may be gained by reducing essential services or eliminating the "fat" in the system.[1] The possibility that quality of care will suffer thus lies at the heart of the questions about the trade-offs between provision of services and cost-effectiveness in any prospective payment system.

Another approach to cost containment is to redesign the delivery of services without sacrificing their scope or access to care. This report evaluates one such effort to restructure services in a public system of mental health care and measures effect of the change on costs, access and distribution of services.

Studies have shown that less intensive care, such as day hospitalization, is at least as effective for seriously ill psychiatric patients as open-ended inpatient stays.[2–10]

With the introduction of day programs into the array of treatment modalities offered, mental health policymakers have assumed that resources would flow naturally from expensive inpatient care to less expensive, community-based care. In fact, the anticipated shift in services does not necessarily occur. Many state systems operate within a fixed budget allocation, yet for the most part they have been slow to shift resources from inpatient care to alternative services. Patterns of service delivery seem to be so entrenched that they drive the public system as much as financial payment mechanisms do. Thus, structural issues must be addressed as part of the effort to shift resources from inpatient hospitalization to alternative care.

A chance to reconsider these issues occurred when a state mental health facility was restructured to substitute day hospitalization and domiciliary care for all patients presenting for inpatient hospitalization. Earlier published reports[11,12] showed the program as both clinically effective and less costly. These early reports used cross-sectional data drawn from the institutional archives; the analyses were limited, as a consequence, to univariate statistical tests of difference, comparing different patients in treatment at several points in time. A decrease in nursing expenses was documented, but the reports did not address cost shifting. This report will address three questions:

- Can day hospitalization and other ambulatory care decrease the per patient cost of care for inpatient treatment?
- If the average cost and length of stay are reduced, what is the effect on selected aspects of care, such as the readmission rate or the use of seclusion?
- If the average annual costs per patient for intensive inpatient care are reduced through the substitution of lower cost alternatives, to what extent will costs be shifted to ambulatory and residential care? To families?

Methods

The Setting

The Massachusetts Mental Health Center is a publicly funded community mental health center serving a racially and economically mixed urban catchment area of 200,000 people. The Center provides a comprehensive range of services, including acute inpatient and long-term care, outpatient and other ambulatory treatment, and community residences. The catchment area system does not have a state hospital to which the Center can transfer patients with chronic severe mental illness. Such patients are treated at the Center, receiving the ambulatory or inpatient service that best fits their needs. The Center receives an annual allocation from the state legislature and is expected to serve (at a minimum) all the poor within the catchment area.

In fiscal year 1982, patient services at the Center were reorganized to substitute day hospitalization for inpatient care. The number of inpatient beds was reduced from 100 to 35. A 40-bed dormitory called the "Inn" was made available to day hospital patients in need of temporary housing. The amount and availability of community-based ambulatory services and residential beds remained virtually the same. The reorganization of services is described in detail

elsewhere.[11,12] The Center has available 17.5 inpatient beds per 100,000 population, which is far below the national rate of 61.3 per 100,000 for state and county mental hospitals.[13] Residential beds within the catchment area system have remained about the same at 45 per 100,000. The area has an active aftercare and case-management program for discharged patients.

Study Design

We compared service utilization costs for one year from the index admission for two cohorts of patients treated at the Massachusetts Mental Health Center: one cohort was treated before (fiscal year 1980) and one after (fiscal year 1984) the restructuring of services and reduction of inpatient beds.

Consecutive admissions in 1980 and in 1984 included individuals sent by the court for observation and competency evaluations, admissions from civil or criminal commitments, individuals transferred from other private or public hospitals, and persons who had no catchment area assignment but were referred by local authorities. Both cohorts drawn by these admissions included patients who received day hospital treatment without any accompanying residential care, but the number of these cases was much lower in 1984 (12 as compared with 44 in 1980). We excluded from each cohort all patients transferred to another facility within 48 hours of admission or hospitalized continuously for the 12-month study period. Excluded patients accounted for 4 per cent of the 1980 cohort and 6 per cent of the 1984 cohort.

The two cohorts were alike on most sociodemographic and clinical characteristics (see Appendix), but the 1984 cohort was slightly younger, with fewer voluntary admissions, fewer high school graduates, more homeless patients, and more patients with a Major Affective Disorder. The latter is thought to reflect changes in diagnostic practice, emanating from the use of DSM III* after 1980.

Data Collection

Using chart abstracts and billing records, we recorded the type and amount of all mental health services used by each cohort member, beginning with the index admission and including all subsequent hospital and community-based services used over the next 12 months. Costs per unit of service were derived by the research staff from the general ledgers of the Massachusetts Mental Health Center and from the vendors of contracted programs. The method for deriving costs and the assumptions that underlie this work are described in an earlier report.[14] Per unit service costs derived for 1980 were inflated forward to 1984 levels using the national Consumer Price Index.

Service unit costs (e.g., inpatient per diem) were merged with utilization data at the patient level, resulting in the cost, by category of care, to treat and support each cohort member. These data were basis for calculations of per admission costs and total annual costs for each patient. This approach permits per patient costs as mean cost per user of a particular category of care and mean cost per cohort member per category of care (all cohort members did not use all services). We have chosen to report the latter because it is the only way to identify shifts of care (and costs) between categories of care.

*DSM III: Diagnostic and Statistical Manual of Mental Disorders, American Psychiatric Association.

Results

Patterns of Utilization

In the 1984 cohort, there was a shift from inpatient to day hospital treatment coupled with residence in the inn, reducing the inpatient length of stay by about half (36 days in 1980, compared with 15 days in 1984). If the "episode of care" is considered to include not just the inpatient stay but the days that followed a transfer to the day hospital, then the total stay in 1984 was 38 days.

A longitudinal analysis also revealed substitution effects. The total number inpatient days accrued by each cohort member over one year decreased from an average of 57 days (for 1.59 admissions) in the 1980 cohort to 21 days (for 1.45 admissions) in the 1984 cohort. Individuals in the 1984 cohort also spent an average of 33 days annually in the day hospital.

As a function of the substitution of less expensive care, per episode inpatient cost dropped from $6,937 to $3,397, a difference of 51 per cent; with the day hospital/inn costs added, the difference shrinks to about 31 per cent, however. If the data are aggregated on an annual level, costs for hospital care (inpatient, day hospital and, in FY84, inn) are reduced from $13,112 in 1980 to $8,204 in 1984.

In order to identify the factors contributing to the differences in annual costs, they were regressed on a model specifying age (and age-logged), race, sex, diagnosis related groups (DRGs), prior living situation, and fiscal year (the dummy variable specifying cohort). Table 1 summarizes estimates of the coefficients. The fiscal year was the major contributor to the variance. To test whether the distribution of costs affected the fit of the model, costs were logged and regressed on the same model, resulting in an R-squared of .129. Using the model as a guide in selecting variables, we tested the cost difference between cohorts after adjusting for DRG, prior living situation, and previous admissions. These cost-adjusted cohort differences shift slightly, as summarized

TABLE 1—Estimates of Variance in Annual per Patient Costs

Model Parameters	Coefficient	Standard Error
Intercept	−10409.27	23779.66

Probability = .0001

in Table 2, but support the finding of differences between cohorts.

Effect on Patient Use of Services

If those changes are detrimental to patients, they are unacceptable, regardless of the financial savings that might accrue under a restructured system. Differences, on two selected measures that might indicate patterns of care detrimental to patients, were analyzed using ANOVA to control for DRG. The results are summarized below.

Seclusion—Limited admission to the inpatient unit would restrict the census to patients with extremely difficult behavioral problems which might lead to an increase in the use of seclusion. In fact, the opposite occurred, suggesting that seclusion is more a function of administrative policy than clinical circumstances. The mean number of seclusions per patient fell from 5.13 in FY80 to 1.05 in FY84. The DRG-adjusted means differed somewhat.

Readmissions—Readmission can be calculated in two ways: over the course of 12 months, and within 90 days of discharge. First, over the course of 12 months the number of readmissions did not increase in the face of much shorter inpatient stays: 1.59 per person in FY80 compared to 1.45 in FY84. DRG-controlled means were not different. Second, a rise in the number of patients readmitted within 90 days of discharge might be interpreted as a measure of failure, whether the rapid return is a result of noncompliance with discharge plans, inadequate discharge planning, inadequate hospital treatment, premature discharge, or reoccurrence of the disorder despite every effort on the part of the clinicians and the patient. We found that from 1980 to 1984, the rate of readmissions within 90 days of discharge, calculated as the proportion of all admissions, did not change: 13 per cent of all readmission in FY80 and 14 per cent in FY84 occurred within 90 days of discharge.

Discharge Status—Data collected on the patients' discharge disposition after the last admission during the study period showed little change across the two cohorts, as summarized in Table 3, with about half the discharges to home and about 11 per cent to community residences. From 1980 to 1984, however, there were small increases in the number of discharges to court and the number of patients who left against medical advice, escaped, or eloped.

Cost Shifting: Annual Community-Based Service Use

Expenditures generated by the two cohorts through the use of mental health services, and residential care during the study period are summarized in Table 4.

Inpatient Costs—Although the per unit cost per day of care increased slightly, the average annual cost per cohort member was reduced because utilization changed: both the length of stay and the number of admissions per patient dropped.

TABLE 2—Adjusted Cost Differences between FY80 and FY84

Adjustment	Point Estimate	95% Confidence Interval
Living situation prior to admission	$4,965	$1,676–$8,254
DRG	$5,007	$2,043–$7,971
No. of previous admissions	$4,703	$4,511–$4,895

*Includes The Inn

Day Hospital Costs—Although the mean costs per cohort member appear to be similar, they represent an example of changes in both per unit costs and in utilization: per unit costs in the 1980 day hospital were much higher, for several reasons: the census was routinely below capacity, the overhead and capital costs were relatively high, and the staffing configuration included more costly professionals. In 1984, the per unit costs were lower because overhead and capital costs were reduced along with the level of professional staffing. At the same time, census was at capacity. Thus, cost shifting in this category of care does not appear to be evident.

Other Ambulatory Costs—These costs account for the use of the Center's ambulatory daytime programs, such as prevocational and rehabilitative services, and social activities. Availability of providers, methods of reimbursement, and operation of the outpatient department and per unit cost of service did not change between the two studies periods. Utilization remained about the same.

Residential Costs—The costs in 1984 rose, as expected, to more than double the 1980 figure. Cost shifting from the inpatient unit to this category of care is evident, although the increase was due not just to the use of the inn. The per unit inflation-adjusted costs of residential housing increased substantially over the period because of rising property values in Boston and improved standards of housing for the mentally ill.

Forensic Hospital Costs—The state forensic facility for the criminally insane is managed by the Department of Corrections but provides a minimal level of treatment for

mental illness. It does not constitute a back door for long-term difficult patients as transfers occur only when that facility agrees to the admission. Mean costs dropped from 1980 to 1984 because of a decrease in utilization.

Family and Social Burden—Costs were calculated as a surcharge to each day hospital or daytime ambulatory treatment day for which no accompanying inn or residential community night were identified. For patients who lived at home during treatment, we estimated the cost to the family based on the work of Frank,[15] who used both personal expenditures and time spent on behalf of the ill family member to arrive at a daily cost to the family. In some instances, patients were living on their own or in a shelter. Costs for these nights were derived from shelter budgets or from SSI/SSDI (supplemental security income) transfer payments, as estimates of minimum costs.

Discussion

Our study has demonstrated a substantial reduction in inpatient costs within a public system of mental health care where both the organizational and fiscal structure created pressures for efficiency. The results suggest that costs can be reduced by differentiating levels of care within a service system, rather than by relying solely on the arbitrary manipulation of reimbursement mechanisms. The study also demonstrated expected shifts in service use from inpatient care to residential programming and day hospital care, reducing somewhat the savings that accrued the reduction in inpatient care.

Our study only begins to address the many complicated questions that arise when attempting to measure the effects of structural change within a system. Findings from a single-site study are undoubtedly compromised by unmeasured site-specific variance. Despite its methodological limitations, our findings confirm what has been the hypothesized cost outcome of the use of hospital "alternatives." Where other studies have selected certain special populations for care in alternate settings, this study took advantage of a program that made no exceptions in program admission, and included all patients needing inpatient care. It remains to be tested whether or not day hospitalization can substitute with equivalent results for individuals treated in other systems.

Certain structural problems will need resolution before widespread use of day hospitals occur. First, centralized administrative and clinical accountability across local catchment area services are thought to be a necessary (but not sufficient) characteristic of effective public mental health systems.[16] Most local systems lack this accountability and are instead a collection of quasi-independent agencies that establish their own program goals for a particular population of clients, and maintain control of admission and discharge from their own programs. Active case-management programs may reduce the access barriers to these programs, but smooth flow of services to the chronically mentally ill remains a major problem in this country.

Second, in many states, a significant problem exists in the management of human resources when phasing down labor-intensive state hospitals and reallocating staff to different programs. The problems arise for several reasons: the hospitals are often in rural isolated communities where the state is the major employer, or there may be strong union activity supporting continuation of jobs historically within the scope of contracts negotiated with the state.

Our findings may be important in considering special financial arrangements for treating the severely and chronically mentally ill in the public sector. One such arrangement that has been proposed is a capitated mental health organization offering a continuum of comprehensive services for a fixed per capita payment.[16–18] The fixed payment provides an incentive to move clients to less costly services as quickly as possible, increasing service efficiency.

Although public capitated systems of care for the chronically mentally ill are rare, one has just been started in Rochester, NY* and several others are in planning stages.** Data from these systems are not yet available. In the absence of evidence from these plans of the likely effect of incentives to provide alternatives to hospitalization, the findings from this study might be of some value. For example, the shortage of public psychiatrists and psychiatric nurses might be alleviated by a system that made the most of their special training, in inpatient units. Other mental health professionals, with limited use of psychiatrists and nurses, could be the primary work force in less medically oriented treatment settings.

In summary, we believe that the key to reducing the use of inpatient treatment and encouraging the use of alternative services lies in structural changes, not in fiscal incentives, that target services more efficiently by matching clinical need with service delivery, rather than by reducing by some fraction all services to all patients. The latter does not address the current situation in the public sector where some patients receive more intensive services than they need and others need more than they are currently receiving.

Second, local service systems might be more efficient if they were clinically and administratively centralized.[19] This combination of factors, rather than fiscal incentives alone, can be used to reshape clinical delivery systems to ensure that the seriously mentally ill are adequately and efficiently served under acceptably standards of care.

The President's Commission on AIDS: What Did It Do?

KRISTINE M. GEBBIE

Introduction

It can be hard to comment on something you have experienced intimately as one of the 13 members of the Presidential Commission on the HIV Epidemic.

The distance of several months is helpful, however, and it has been educational for me to reflect on the process.

The Commission was made up of 13 individuals. By non-mutually exclusive categories, we were eight men, five women, one Black, one gay, five physicians, two nurses, two academics, one minister, one legislator, one publisher, five business executives, one government official, one sailor; geographically, seven from New York/Washington, three from the Midwest, two from the West Coast, one Southerner. There is no way we could be representative of the nation, but we tried to be conscious of all segments of our society. Several were entities "known" to the Reagan Administration, some not; some had congressional support, some were known to their colleagues, some were a category about which it could be said "we've got to have one of them," etc. What I brought to the Commission's process was exposure to the public health system, separation of illness care from prevention, and perhaps some broadening of awareness of the complexity of experience with human immunodeficiency virus (HIV) and public health policy within state health officials association, and in my own State. Perhaps it is important that I did *not* come from New York, California, Florida, New Jersey, Texas. Many people do not identify with those states, and although they have led in this epidemic (both in problem and solutions) their experience must be translated to be useful to others.

The charge to the Commission was enormous: "advise the President and Secretary of Health and Human Service and other relevant cabinet heads on public health dangers including medical, legal, ethical, social and economic impact, from the spread of the HIV and resulting illnesses."[1] Specific areas requested included: "recommend measures that Federal, State and local officials can take to protect the public . . . to assist in finding a cure and . . . to care for those who have the disease."[1] The Commission was further charged to "evaluate efforts by educational institutions . . . analyze efforts currently underway by Federal, State, local authorities, examine long term impact on care system . . . review U.S. history of dealing with communicable disease . . . evaluate research activities . . . identify future areas of research . . . examine policies for development of drugs . . . assess progression of AIDS among the general population and subgroups . . . study legal and ethical issues . . . review the role of the US in the international pandemic."[1]

The Chairman, when I was appointed, was an Admiral asked by his Commander-in-Chief to complete a mission. There were two key elements on which he insisted: 1) credible testimony in public hearings would be the basis for recommendations (rather than any preconceived ideologies of Commissioners); and 2) the regular appearance of HIV-infected persons would put more abstract issues into the human perspective.

Things the Commission did not do

It did not do much, if anything, to bring the President into the HIV response, possibly because he is so shielded by the conservative voice. To no avail, we criticized the Reagan Administration, suggested attitudes and approaches not comfortable to its leaders, asked for monies that had not been authorized. It was probably too much to hope that there would be a sudden turn around. Yet it might have been a nice finish if we at least could have met in the Rose Garden.

Neither did we break the Congressional log jam or budget. There was no immediate action to pass the Americans with Disabilities Act[2] or pour monies into drug treatment. Yet the Commission was clear that both actions were critical first steps. A word about each:

- The Americans with Disabilities Act recommendation was the cause of the most serious disagreement in the final report, with a split vote. I believe the debate was not about fighting or not fighting discrimination, but on this particular act as the vehicle. It takes a broad, "civil rights" approach to *all* disabilities, not setting the HIV-infected apart. The majority of the Commissioners viewed it as the most equitable and efficacious way to proceed. Chief opposition comes from the business community which saw this approach as "too costly."
- Massive increase in drug treatment (to the level sometimes called "on demand") requires re-thinking substance abuse as a chronic condition which may need treatments at several points in an individual's life. We must become serious about attacking addictions with *all* available weapons, not just police action and "just say no" campaigns.

We did not really resolve what I think is going to be a major subject of debate in the coming months: the appropriate response to a health care worker exposed to a potentially infectious substance, and the appropriate behavior of an infected health care worker. The Commission report includes some nice paragraphs on the subject, talking about "workers' right to know" (long a favorite public health phrase), confidentiality, prospective policies regarding infected workers. Listening to physicians, nurses, EMT's (emergency medical technicians), their spouses, lovers, employers over the past few weeks, it becomes clear to me that this issue is far from

Sero Survey of Human Immunodeficiency Virus Infection in Women at a Family Planning Clinic: Absence of Infection in an Indigent Population in San Francisco

PHILIP D. DARNEY, MD, WENDIE MYHRA, MSN, ELIZABETH S. ATKINSON, BA, AND JANE MEIER, MPH

Abstract: To determine the seroprevalence of human immunodeficiency virus (HIV) in contracepting women, 1,308 consecutive attendees at an inner-city family planning clinic completed a risk factor questionnaire and were then asked to have an HIV test. None of the 1,000 women tested was seropositive. Preventive efforts in family planning clinics are likely to be productive because few contraceptors, including those with risk factors, are already infected. The factors which determine differences in HIV positivity between childbearing and contracepting women, who are similar in demographic and HIV risk characteristics, warrant further investigation. (*Am J Public Health* 1989; 79:883–885.)

Introduction

Concern is expressed[1–3] over the possibility that the human immunodeficiency virus (HIV) will rapidly become more prevalent in women who can then pass it to their sexual partners[4–6] and babies.[7–11] Rates of HIV positivity in childbearing women range from less than one per 1,000 in suburban and rural populations[12] to as high as two per 100 at inner-city municipal hospitals.[13] Such determinations of HIV infection in women have generally relied on cord blood or heel stick surveys. Few investigations have screened actively contracepting women and avoided, or accounted for, possible selection bias. None have systematically assessed the prevalence of risk factors in such a population. Since 55 percent of US women aged 15 to 44 are active contraceptors,[15] a family planning clinic population may more accurately reflect the HIV status of women of childbearing age than do other populations. This seroprevalence study assessed the level of HIV infection in relation to risk factors for this infection at a family planning clinic serving the indigent women of a city where HIV infection is endemic in homosexual males.

Methods

The study was conducted from November 1987 to April 1988 in an urban hospital-based family planning clinic. In 1987, 93 percent of the clinic's 3,116 active patients lived in households with incomes beneath the "poverty level"; 12 percent used condoms with or without spermicidal foam, 20 percent used diaphragms and other barrier methods, 65 percent used oral contraceptive pills, and 3 percent used IUDs (data available on request to authors). As part of routine evaluation, all women attending the clinic completed a confidential, self-administered questionnaire, had blood drawn by lab personnel, and were then seen by a clinician. The questionnaire was designed to elicit a history of intravenous (IV) drug use, blood transfusions between 1979 and 1985, artificial insemination between 1979 and 1985, sexual practices including sexual contact with persons diagnosed with AIDS (acquired immunodeficiency syndrome), ARC (AIDS-Related Complex), or hemophilia, sexual contact with IV drug users, sexual contact with bisexual men, and sexual contact with more than five partners in any one year since 1979. Clinicians reviewed the women's responses with them and provided information on HIV infection, prevention, and implications of antibody testing. The women were then asked to permit an HIV test of their blood. The study was approved by the Committee on Human Research of the University of California, San Francisco.

If women consented to an HIV test, an anonymous number coding system permitted them to obtain test results. Blood tests were performed only for women who consented, but demographic and risk factor information was collected for both the women who agreed to testing (participants) as well as those who did not (nonparticipants). Blood specimens were collected aseptically and stored at 4°C pending transport for analysis.

The Viral and Rickettsial Disease Laboratory, Division of Laboratories, California State Department of Health Services analyzed the blood samples using EIA Dupont and Genetic Systems kits. The laboratory analyzed repeat positives with IFA reagents, and if EIA and IFA did not agree, performed Western Blot.

Results

A total of 1,308 women completed questionnaires during the study period, which continued until 1,000 women agreed to participate in the study. There were no significant differences in demographic characteristics of the 1,000 participants and the 308 nonparticipants (Table 1). Participants were more likely to report histories of STDs (sexually transmitted diseases) (Table 1), riskier behavior, and have at least one AIDS risk factor than were nonparticipants (Table 2). Although 14 percent of the participants claimed one or more risk factors, none had HIV antibodies.

TABLE 1—Serosurvey Participants and Nonparticipants by Selected Demographics

Characteristics	Participants (N = 1000)	Nonparticipants (N = 308)
Ethnicity		
% Latino	59.3	56.8
% White	17.3	17.2
% Black	15.3	15.9
% Asian	5.9	6.8
% Other	2.2	3.2
Mean Age (years)	26.3	26.4
Mean Live Births	1.4	1.5
Mean Elected Abortions	0.9	0.8
History of STDs (%)	13.7	6.5

TABLE 2—Number of Risks and Specific Risks Reported by Serosurvey Participants and Nonparticipants

	Participants (N = 1000)		Nonparticipants (N = 308)	
Number of Risk Factors	N	%	N	%
One Risk Factor	101	10.1	15	4.9
Two Risk Factors	30	3.0	3	1.0
Three Risk Factors	7	0.7	0	0.0
At Least One Risk Factor	138	13.8	18	5.8
No Risk Factors	830	83.0	279	90.6
Some Not Reported; all others negative	32	3.2	11	3.6
Risk Factors				
IV Drug Use by Self or Partner	26	2.6	0	0.0
5 or More Partners/Year	72	7.2	7	2.3
Partner with AIDS or ARC	1	0.1	0	0.0
Blood Transfusion, 1979–85	19	1.9	3	1.0
Bisexual Partner	11	1.1	0	0.0
Partner Possibly Bisexual	53	5.3	11	3.6

Caucasians and Black women had much higher incidence of risks than did Latinos and Asians (30.1 percent and 20.3 percent versus 7.9 percent and 6.8 percent, respectively) (Table 3). Caucasians were the most likely and Latinos least likely to report multiple AIDS risk factors. A total of 237 women (24 percent) chose to return for their results. This choice was positively correlated with the level of risk: those with greater numbers of risks, those with self or partner IV drug use, and those who had received blood transfusions were the most likely to return for the HIV test results.

Discussion

There are several possible explanations of the absence of seropositives in our study population: We surveyed a low-risk population; seropositivity is uncommon among San Francisco women in general, including those who report risk factors; or women attending family planning clinics may behave in ways which place them at lower risk than their counterparts in the childbearing population.

Overall, fewer women reported risk factors in this study than in other studies. The fact that the present questionnaire was self-administered may have further increased the chance that some risks were not reported, due to confusion, oversight, or embarrassment. However, other sero surveys have suggested that self-reported risk factors are unreliable predictors of HIV positivity,[3,11,13] so this risk assessment of San Francisco women may not represent their actual risk. Because 85 percent of the women attending this clinic used contraceptive methods not known to protect against HIV infection (pills, IUD, or diaphragms), the use of contraception by itself seems an unlikely explanation of lower risk. Only the history of intravenous drug use was a significant predictor in Quinn, *et al*'s,[3] multivariate regression analysis of risk factors. The fact that most IV drug users do not use traditional family planning services means that we did not survey many of the women who are at the greatest risk.

These observations suggest that HIV seropositivity is uncommon in San Francisco family planning clinics, and thus universal HIV screening in these clinics is unwarranted. Instead, these are ideal places for educational efforts to reduce heterosexual transmission of the virus. These results also suggest that further examination of the behavior characteristics which differentiate women who attend family planning clinics from those in the childbearing population might help identify patterns of behavior which place women at lower risk of heterosexual HIV transmission. Because previous studies[3,12,13] were conducted in East Coast cities only, studies of other West Coast cities are needed to determine if HIV infection differs between contraceptors and the remaining female population of childbearing age. In addition, innovative outreach programs are urgently needed to educate those women who use, or whose partners use, IV drugs of the risks of HIV infection to themselves and their fetuses, and to provide contraception to such women.

Stress Reduction Training Changed Number of Sexual Partners but Not Immune Function in Men with HIV

THOMAS J. COATES, PHD, LEON MCKUSICK, PHD, RICHARD KUNO, AND DANIEL P. STITES, MD

Abstract: We tested the impact of stress management training on sexual behavior and immune functioning in 64 gay men infected with human immunodeficiency virus (HIV). Subjects randomized to the stress management group met for eight two-hour sessions and one all day retreat to learn systematic relaxation, health behavior change, and stress management skills. Compared to those randomized to a wait list control, treatment subjects reported significantly fewer sexual partners in the prior month at post-test (1.10 vs 2.29 for controls). There were no differences between groups in lymphocyte numbers and function. (*Am J Public Health* 1989; 79:885–887).

Introduction

Significant associations between stressors, decrements in immunological function and clinical disease have been reported.[1,2] Relaxation techniques,[3] humorous film stimuli,[4] and operant conditioning procedures[5] may contribute to immunoenhancement. Levy and Ziegler[6] proposed that HIV (human immunodeficiency virus) infection is an opportunistic disease, progressing to clinical AIDS (acquired immunodeficiency syndrome) only in those who are immunocompromised by other factors. To date, several co-factors for disease progression have been identified, including time of infection, age, incidence of gonorrhea, and use of hallucinogens.[7–9] Antigen exposure, drugs and alcohol use, nutrition, and health habits as well as psychosocial stress are also posited cofactors.[2] Tension reduction has been related to levels of sexual activity which may transmit HIV.[10] This study was designed to test experimentally the hypothesis that group stress reduction training will lead to improvements in immune function and reductions in unsafe sex.

Methods

One hundred twenty men responded to a brief article placed in a local San Francisco gay newspaper asking for volunteers. Subjects were selected who: were seropositive for HIV; had not experienced oral candidiasis, hairy leukoplakia, recurrent herpes infection, or herpes zoster; and who were not already practicing meditation regularly. A total of 64 men (mean age = 34.9 years) who met the criteria completed baseline questionnaires and venipuncture. Subjects were then randomized into treatment or control groups. All subjects signed a statement of informed consent approved by the Human Subjects Review Committee of the University of California-San Francisco. Immediately following the termination of each treatment, all experimental and control subjects were re-assessed on the behavioral and immunological measures. Immunological assays included enumeration of lymphocytes and subsets.[11] In addition, we completed a number of functional measures of immunity. These included: Natural killer cell function,[12] lymphocyte response to Concanavalin A (ConA) and Candida antigen[13] and to cytomegalovirus (CMV),[14] and serum Immunoglobulin A (IgA).[15] Laboratory staff were blinded as to subject name and assignment.

Stress reduction training was completed in two-hour sessions once per week for eight weeks, with one all day retreat after week 4. The goals of the sessions were:

- learning systematic relaxation—through use of group time and take-home tapes, to attain some systematic relaxation for each individual every day;
- health habit change—including execution of behavioral contracts around diet, rest, exercise, drug and alcohol use, and smoking;

- learning skills for managing stress—including the stress of being seropositive through the use of group discussion, teaching, and modeling.

We used analysis of covariance with the baseline as the covariate to test post-treatment differences.

Results

Presented in Table 1 are post-test differences in adjusted means with 95% confidence intervals. Treatment subjects reported fewer sexual partners at post-test than did control subjects. Only 14 per cent of subjects reported practicing unsafe sex at baseline, with no differences between groups. At post-test, 15.9 percent of subjects reported practicing unsafe sex, again with no difference between groups. There were no post-test differences in measures of immune number or function.

Discussion

Reducing the number of sexual partners may be important for HIV seropositives. Polk, *et al*,[16] reported that number of partners was a risk factor for disease progression among infected men. Hessol, *et al*,[9] reported that incidence of gonorrhea predicted disease progression. The ability of this kind of treatment to reduce multiple partner sex and unsafe sex should be explored further.

There are several reasons why these negative immune outcomes may have occurred:

- We measured immune function one to four days following the termination of the group. Sadness at termination may have caused deterioration in immune function.
- Immune function may not be influenced by stress or stress reduction in the presence of HIV infection.
- Single measures of immune function may not be sensitive to the subtle effects of stress management. Multiple assessments may be needed to get stable measures.
- The psychosocial intervention may not have been sufficiently potent. Extremely intense interventions are needed to bring about clinically significant changes in risk factors for ischemic heart disease.[17]
- The nature of the group may also have induced stress as the leaders attempted to reduce it.

Whereas the presence of other infected men helped individuals to recognize and confront the psychological issues related to AIDS, participation also focused closely on immune function, which can provoke anxiety. Awareness of HIV seropositivity, a screening variable for the study, may further increase anxiety. This may be indicative of the dilemma faced by members of the San Francisco community: as individuals seek to cope with an epidemic in their environment and protect their own health, the anxiety associated with coping collides with the need to reduce stress and conduct good health maintenance.

Characteristics of Self-Selected Responders to a Health Risk Appraisal: Generalizability of Corporate Health Assessments

WENDY D. LYNCH, PHD, THOMAS J. GOLASZEWSKI, EDD, ANDREW CLEARIE, MSPH, AND DONALD M. VICKERY, MD

Abstract: Selected characteristics and total medical claims of health risk appraisal (HRA) responders and non-responders were compared in a sample of employees having a three-year employment and claims history. HRA responders were younger and more likely to file medical claims than non-responders. Although mean medical claims were greater for HRA responders than non-responders, when adjusted for age and sex this difference reflected the proportion of employees reporting claims, not a difference in the claims amount. (*Am J Public Health* 1989; 79:887–888.)

Introduction

There is conflicting information about the characteristics that influence participation in health promotion activities,[1] although it has been suggested that participants are healthier than non-participants.[1–3] This assumption has not been documented by differences in health status or health costs however. To address this concern, the present investigation tests the null hypothesis that independent of their age, sex, or job type, health risk appraisal (HRA) responders are similar to HRA non-responders with respect to health costs.

Methods

The generalizability of HRA data in our present setting was determined by the degree of similarity between the self-selected HRA responders and non-responders.

The subject population consisted of full-time employees of the Travelers Companies home office, having at least a three-year employment history as well as group health insurance (not health maintenance organization) (N = 6,989). All eligible employees were requested to complete a voluntary HRA instrument, the Lifescore Plus questionnaire. Comparisons between HRA responder (2,600) and HRA non-responder (4,389) group characteristics were based on personnel information, sex, age, and job type (salaried or hourly).

The average amount paid for medical claims over the three-year period prior to administration of the HRA was calculated for each insured employee. Only claims for the subjects (not for spouses or dependents) were included. The group insurance plan covered almost all medical expenses (with limits on out-of-pocket co-payments) including ambulatory care, medications, surgery, and hospital and home health care services, up to a lifetime maximum of $2 million. In addition, the insurance plan paid 80 per cent of inpatient psychiatric expenses and 50 per cent of outpatient mental health expenses. Employees were required to pay $100 cash deductible per year and additional deductible amounts for each hospital confinement. Expenses that were not covered included routine medical tests, service-related disability expenses for veterans, and expenses covered under workers' compensation. Insured employees having no record of filed claims were assigned an average of zero dollars.

Because the claims data were extremely skewed, several forms of this variable were examined. In one form, to account for the disproportionate weight carried by the highest cases, the top 1 per cent of the cases (ranging from $5,971 to $41,711) were removed (N = 70). In another form, average claims values were adjusted (cube root transformation) to reduce the extremely skewed nature of the data. Mean claims for the HRA responder and HRA non-responder groups, in their adjusted and unadjusted forms, were compared using a hierarchical multiple regression to remove the influence of age and sex differences.

Results

HRA responders differed from non-responders in several respects. HRA responders (39.7 ± .21 years) were younger on average than non-responders (41.1 ± .17 years). A greater proportion of salaried and a lesser proportion of hourly employees responded to the HRA (61 ± 0.95 per cent salaried in the HRA responder group vs 48 ± 0.75 per cent). Males and females were equally represented in both groups. Interestingly, HRA responders were more likely to file health

© 1989 American Journal of Public Health 0090-0036/89$1.50

claims (78 ± 0.8 per cent) than non-responders (72 ± 0.7 per cent). Excluding the outlying cases, mean claims for the HRA responder and non-responder groups were $424.52 (median = $89) and $399.67 (median = $77), respectively.

Overall, HRA responders experienced higher average claims than non-responders after means were adjusted for age and sex differences. Type of employment (salaried or hourly) had no independent bearing on claims costs. Table 1 shows the estimated cost difference between HRA responders and non-responders for all insured subjects using claim costs both in their original form and without the outlying 1 per cent of the cases. Using the more conservative estimate, the HRA responder is expected to cost almost $40 more per year than a non-responder of the same age and sex. However, when only those filing claims were compared the difference in average claim amounts was no longer evident.

Discussion

The results of these simple demographic and medical cost comparisons contrast with previous reports concerning participants in worksite health promotion activities. First, there were distinct characteristic differences between those who selected to respond to HRA and those who selected not to respond. Whether these differences are consistent with HRA participation in other settings is not known.

Second, earlier suggestions that participants in organized health promotion programs are healthier than non-participants and may use fewer medical services were not substantiated in our research population. HRA responders were more likely than non-responders to file medical claims, yet for those who filed claims, costs were similar. Put simply, the health profile for HRA responders cannot be generalized safely to the larger employee population.

TABLE 1—Estimated Medical Claims Differences between HRA Responders and Non-Responders (Holding Age and Sex Constant)

	Cost Difference (Mean Responder Claims—Mean Non-Responder Claims)	
	Cost Difference	(95% CI)
All insured (including outliers)	$70.55**	($35.34, $105.76)
All insured (excluding outliers)	$38.43**	($19.11, $57.75)
Those filing claims (including outliers)	$36.81	($−9.24, $82.86)
Those filing claims (excluding outliers)	$ 3.87	($−20.89, $28.63)

**Cost differences significantly greater than zero.

The observed relationship between HRA response and health claims lends itself to several possible explanations. Perhaps HRA responders are overly concerned about health and more likely to seek health services. On the other hand, those in poor health may have greater motivation to respond to HRA. Another possibility might be that, ignoring health status, some individuals dislike paperwork and are less likely to fill out forms of any kind, HRA instruments and reimbursement forms included. Whatever the explanation, HRA responders seem to behave differently than non-responders.

Results of the comparisons based on transformed claims data were consistent with the findings above, with respect to the hypotheses that were tested. Because the data conform to the assumptions on which linear regression are based, the transformed claims produced better model fit and reduced the inflation in estimates of claims differences. These issues were not addressed here, but pertinent findings are available upon request to the authors.

We recognize that the claims records used in this investigation represented only those services that were reported by the employees, and that specific diagnoses could not be identified. Almost all medical expenses were covered by the plan, with a few exceptions that had no obvious relevance to the comparisons made in this investigation. Due to normal procedures, a claim must have been filed by the employee in order for the employee to receive payment for expenses. We cannot know whether true health expenses were underestimated because of claims not filed.

Because it may not be possible to generalize to HRA non-responders, health promotion practitioners should place a high priority on encouraging high response rates from their employees. In addition, repeated administration of HRA within the same company may reflect both health status changes and changes in self-selection so that a true indication of short-term changes in behavior can be inferred only by comparing individuals with themselves.

Personality Risk Factors for Cocaine Abuse

WILLIAM R. YATES, MD, MS, ANN IVY FULTON, BSW, JANELLE M. GABEL, RN, AND CLINT T. BRASS

Abstract: To evaluate the role of personality in cocaine abuse, 59 adults meeting DSM-III criteria for cocaine abuse were compared to similar-aged non-cocaine alcohol abusers and community controls on a DSM-III measure of personality. Cocaine abusers were more likely than non-cocaine alcohol abusers to display narcissistic personality traits (Odds ratio 6.86, 95% CI = 4.52, 15.60). (*Am J Public Health* 1989; 79:891–892.)

Introduction

Although recent surveys suggest a decrease in recent cocaine use among high school seniors,[1] cocaine abuse continues to be a current problem for over one million Americans.[2] With widespread cocaine abuse, cocaine-related emergencies and death have tripled over a five-year period.[3] The illusion of cocaine as a "safe" drug has evaporated as pure, more potent, and less expensive forms of cocaine have evolved. Cocaine abuse is now recognized as a significant cause of psychiatric and medical morbidity.[4]

Psychiatric epidemiologic surveys point to common associations (comorbidity) between major psychiatric disorders and substance abuse.[5] For alcohol abuse in the community, antisocial personality disorder is a frequent comorbid condition.[6] The role of personality in cocaine abuse is less well-defined. Uncontrolled descriptive studies have found high rates of some personality disorders in clinical samples of cocaine abusers.[7] To further evaluate personality as a risk factor for cocaine abuse, we studied the personality of a group of cocaine abusers compared to non-cocaine alcohol abusers and community controls.

Methods

Cases and psychiatric controls were obtained from an unselected series of 229 substance abusers seeking inpatient treatment at one of three Iowa City, Iowa treatment facilities. Cocaine abuse was defined according to the criteria of the Diagnostic and Statistical Manual of Mental Disorders, Third edition (DSM-III), using the Diagnostic Interview Schedule.[9] Fifty-nine (32.9 per cent) of the sample met criteria for cocaine abuse and were identified as cases. A group of 47 similar-aged substance abuse controls were identified by meeting DSM-III alcohol abuse or alcohol dependence criteria. A minority of substance abuse controls had used cocaine but none met criteria for abuse.

The Personality Diagnostic Questionnaire (PDQ) was administered to all cases and controls.[10] The PDQ assesses personality using 11 non-exclusive categories in a 152-item forced choice, true-false self-report questionnaire. The DSM-III describes 11 personality categories grouped into three clusters based on similar psychological constructs with cluster A denoting eccentric features, cluster B denoting flamboyant features, and cluster C denoting anxious features. Although the methodology of assessing personality by DSM-III criteria has only recently emerged, the PDQ has some evidence for test-retest reliability for many personality disorders[11] and has demonstrated prognostic validity in patients with major depression.[12] Additionally, the PDQ has been used in psychiatric clinical populations[13] and has been used in a community survey.[14] Sixty-nine similar-aged community controls without cocaine abuse were identified from this previous community survey using the PDQ. Cases and both control individuals were all identified blind to their PDQ results.

The distribution of personality disorder and traits is influenced by the respondent's gender.[15,16] The Mantel-Haenszel chi-square statistic was calculated to correct for group sex differences. Odds ratios were calculated with 95% confidence intervals using the method of Woolf[17] with calculations of combined sex-weighted odds ratios.[18]

Results

The count and ages (standard deviation) for individual groups by sex were:

cocaine abusers—men N = 36, 28.0 (6.3 years), women N = 23, 26.0 (6.4 years)

alcohol abusers—men N = 22, 31.0 (6.7 years), women N = 25, 28.6 (6.2 years)

community controls—men N = 30, 29.8 (4.5) and women N = 39, 22.2 (4.3).

The three groups were all largely Caucasian in race: cocaine abusers 84.7 per cent, alcohol abusers 87.2 per cent, and community controls 94.2 per cent.

Personality comparisons between groups are shown in Table 1. Narcissistic personality was more common in cocaine abusers compared to alcohol abuse controls (32.2 per cent vs 6.4 per cent, $X^2 = 10.92$, Odds ratio = 6.98, 95 per cent CI = 1.26, 37.1). Additionally, cocaine abusers were more likely than alcohol abusers to report schizoid features (13.5 per cent vs 0 per cent, Fishers exact one-tailed p = .042). Cocaine abusers demonstrated multiple personality features compared to community controls. Cluster B disorders were especially more prevalent among the cocaine abusers compared to community controls (79.6 per cent vs 10.11 per cent, $X^2 = 61.4$, Odds ratio = 36.0, 95 per cent CI = 8.54, 151.00).

Discussion

This is the first study, of which we are aware, that examines the prevalence of all 11 DSM-III personality disorder types in a sample of cocaine abusers compared to both substance abuse and community controls. Narcissism, as assessed by the PDQ, is very infrequently found in non-cocaine substance abusers and community controls. The symptoms of narcissism reflect an emphasis on personal attention and power and are assessed in the PDQ with true responses to questions such as, "I frequently make myself the center of attention" and "I find myself thinking about how great a person I am, or will be." Cocaine abusers have often described a sense of euphoria and power with cocaine

High Prevalence of Hepatitis B Virus Infection in Rural Black Adults in Mseleni, South Africa

SALIM S. ABDOOL KARIM, MB, ChB, RAJENDRA THEJPAL, MB, ChB, AND BIPRAJ SINGH, Dip Clin Pathol/Virol

Abstract: A community-based study in northern Natal/KwaZulu, South Africa, assessed the prevalence of hepatitis B virus (HBV) infection in rural Black adults. The prevalence of HBV carriers was 4.4 percent in women (N = 342) and 7.1 percent in men (N = 99). At least one marker of HBV infection was present in 81 percent of women and 86 percent of men. The relative risk (RR) of HBV marker positivity in women due to scarification, adjusted for the presence of pierced ears, was 1.37 (95% CI = 0.9, 2.1). Risk factors such as scarification and pierced earlobes need to be further investigated to assess their role in the transmission of the HBV. (*Am J Public Health* 1989; 79:893–894.)

Introduction

Hepatitis B virus (HBV) infection has a worldwide distribution and is especially important in Africa.[1] Asymptomatic HBV carriers comprise the main infectious reservoir responsible for transmitting the virus to susceptible individuals in the population. HBV carriers also suffer higher morbidity and mortality due to chronic forms of hepatitis, cirrhosis, and primary hepatocellular carcinoma.[2]

The highest prevalence rates of HBV carriers have been reported from southeast Asia and sub-Saharan Africa. In rural Thailand, a 7.3 percent prevalence of hepatitis B surface antigen (HBsAg) has been reported[3]; in Africa the HBsAg prevalence rates vary from 2.1 percent in Kenya[4] to 12.1 percent in Somalia.[5]

In South Africa, Bersohn, *et al*,[1] observed a 2 percent prevalence of HBsAg in urban and 7 percent in rural Black South African blood donors. Prozesky, *et al*,[6] found adult HBsAg prevalences of 14.6 percent in men and 4.6 percent in women from the rural area of Kangwane. In Kavango, a rural area of northern Namibia, a 13.6 percent prevalence of HBsAg has been reported.[7] These estimates, however, are likely to be biased by self- and social-selection in samples of blood donor populations and health services users.

A previous study of 238 schoolchildren in Mseleni showed a HBsAg prevalence of 18.4 percent, one-half of whom were also hepatitis B e antigen (HBeAg) positive.[8] To our knowledge no community-based studies have been undertaken to assess the prevalence of HBV infection in rural Black adults in South Africa. The purpose of this investigation was to assess the prevalence of adult HBV carriers in Mseleni, the proportion of female HBV carriers who are HBeAg positive, and the possible role of ear piercing and scarification in the transmission of the virus.

Methods

Field work was conducted in November 1985 in Mseleni, a rural area in the Ngwavuma district of northern Natal/KwaZulu on the east coast of South Africa. Mseleni is similar to many other rural areas in South Africa.

Each household in the district is visited regularly by field workers of the malaria control program as part of the ongoing surveillance for malaria in the area. For the purposes of this study, the typical arrangement of four to eight huts built in a circle with a common cooking area in the center is regarded as a household. Household size varies from three to 32 persons. There are approximately 1,000 such households in Mseleni, many of them being inaccessible by road. Piped water is not available. Individual households are isolated and there are often considerable distances between households.

About 60 percent of households are accessible by jeep, and these served as the primary sampling units. A multistage sampling technique was used. One adult from each accessible household was randomly selected by the field worker after he had assigned a number to each adult in the household as he encountered them during his house visit. After informed consent was obtained, the subject's name, sex, and household number were recorded and each person was examined for evidence of scarification and pierced ears. A single 5ml tube of blood was drawn for HBV studies at the conclusion of the interview.

All blood specimens were centrifuged within 24 hours, and the sera stored at −20°C and transported on dry ice to Durban (approximately 500 km away). All sera were tested by radioimmunoassay for HBsAg, hepatitis B surface antibody (HBsAb), and hepatitis B core antibody (HBcAb). Sera positive for HBsAg were further tested for IgM-class HBcAb, HBeAg and hepatitis B e antibody (HBeAb) (AUSRIA-II, AUSAB, CORAB, CORAB-M and ABBOTT-HBe; Abbott Laboratories, Chicago, Illinois). Calculations of the confidence intervals (CI) for proportions[9] and relative risk (RR) of the Mantel-Haenszel weighted risk ratio[10] and tests for statistical interaction were done by standard methods.

Results

A total of 441 subjects were studied, of whom 342 (77.6 percent) were women. The prevalence of HBsAg was 7.1 percent in men and 4.4 percent in women (RR = 1.6; 95% CI = 0.7, 3.9). At least one serological marker was positive in 81 percent of the women and 86 percent of the men (Table 1)

TABLE 1—HBV Serological Markers in Black Adults in Mseleni, South Africa

HBV Marker	Female (N = 342)	Male (N = 99)	Combined (N = 441)
HBsAg+	15 (4.4)*	7 (7.1)	22 (5.0)
HBsAb+/HBcAb+	261 (76.3)	78 (78.8)	339 (76.9)
Any Marker Present	276 (80.7)	85 (85.9)	361 (81.9)
All Markers Absent	66 (19.3)	14 (14.1)	80 (18.1)

*Number (%).

indicating previous or current HBV infection.

Only one of 15 (6.7 percent) HBsAg positive women was HBeAg positive (95% CI = 0, 28). The remaining 14 women and all seven men who were HBsAg positive were HBeAb positive and HBeAg negative. All HBsAg positive subjects were negative for IgM-class HBcAb, confirming that they were HBV carriers.

The overall response rate was estimated at between 60 percent and 70 percent. The mean age of the women studied was 43.1 years (standard deviation, 16.7 years; range, 16–88 years). Most men from the rural areas of South Africa work in the large urban centers during the year and were therefore under-represented in our study. Given this selection bias, the data on men were not further analyzed.

The prevalence of scarification was high in both HBV marker positive (96.7 percent) and negative (90.9 percent) women. The RR of being HBV marker positive was 1.36 (95% CI = 0.9, 2.1) for scarified women, taking women without scarification as the reference group. After adjustment for pierced ears, the RR of being HBV marker positive due to scarification was 1.37 (95% CI = 0.9, 2.1).

There is no evidence of positive or negative interaction between the effects of scarification and pierced ears, under a multiplicative model.*

Discussion

While a response rate of 60–70 percent is less than ideal, such a response rate is good in a rural setting which has many communication and transportation problems. Even though our sample underrepresents certain groups such as men and disabled or sick women, we believe it provides a reasonably accurate estimate of the prevalence of HBV carriers in healthy women in Mseleni.

One can infer, despite the small number of HBsAg positives, that only a small proportion of the HBsAg positive women are also HBeAg positive. The low frequency of HBeAg positivity and the high proportion of HBeAb positivity in women HBV carriers holds for women of reproductive age; the exclusion of older women does not alter the carrier rates significantly. This finding provides one explanation for the very low levels of vertical transmission in southern Africa, since the presence of HBeAg in the mother is important for transmission of HBV infection to the newborn.[11]

The high prevalence of HBeAg (50 percent) in Mseleni school girls who are HBV carriers[8] compared to the low prevalence of HBeAg in adult women (6.7 percent) suggests a high HBeAg seroconversion rate in young women. Another explanation for this difference would be a generation effect but this is unlikely considering that the HBV exposure rates in Mseleni school girls and adult women were 65 percent and 81 percent, respectively.

In southern Africa, the predominant mode of transmission is horizontal.[4] Homosexuals and intravenous drug users are relatively less important risk groups in this region.[12] The exact mechanism of transmission is unknown.

*Data available on request from author.

Both scarification[13] and pierced ears[14] have been previously implicated in the transmission of HBV. The lack of strong associations between these risk factors and HBV marker positivity in our data is possibly due to the high prevalence of scarification (95.6 percent) and pierced ears (90.6 percent). However, the upper limit of the 95% confidence interval for the RR of being HBV positive due to scarification is 2.1, which is consistent with associations reported in our previous study of Black children in South Africa.[8] Possible risk factors such as scarification and pierced earlobes need to be further investigated to assess their importance in the transmission of the HBV.

HBV infection is endemic in Mseleni. Mass vaccination campaigns to reduce the size of the susceptible population as well as health education campaigns aimed at reducing the risk of infection need to be mounted regardless of our current ignorance of specific risk factors.

ACKNOWLEDGMENTS

We are indebted to the KwaZulu Department of Health for permission to work in Mseleni, and to the following people for their valuable advice and assistance: Professors C.H.J. Schutte, H.M. Coovadia, M.W. Susser and J. van den Ende; Doctors I.M. Windsor, R.M. Cooppan, A. Fouche, S. Vermund, G.M. Short and D.B.T. Hackland; Miss J. Nkomokazi, Miss E. Cacata, Mr. W. Gopaul, Mrs. C.C. Vinsen, and Mr. Mngomezulu and his malaria control team. This project was conducted at the Research Institute for Diseases in a Tropical Environment and was funded by the South African Medical Research Council.

Evaluation of Radiation Safety in 29 Central Ohio Veterinary Practices

SHERYL A. MORITZ, MS, JOHN R. WILKINS III, DrPH, AND WILLIAM D. HUESTON, DVM, PhD

Abstract: A sample of 29 veterinary practices in Central Ohio were visited to assess radiation safety practices and observance of state regulations. Lead aprons and gloves were usually available, but gloves were not always worn. Protective thyroid collars and lead glasses were not available in any practice, lead shields in only five practices, and lead-lined walls and doors in only two practices. Eighteen practices had none of the required safety notices posted. (*Am J Public Health* 1989; 79:895–896.)

Introduction

Exposure to ionizing radiation is a potentially serious occupational health hazard. At high doses it is carcinogenic, mutagenic, and teratogenic,[1] but the effects at low doses are much less certain.[2] The severity of the effects appears in most circumstances to be no greater than a linear relationship to dose with no threshold value. A major source of human exposure is the medical utilization of diagnostic and therapeutic radiography.[1] Veterinarians represent a subgroup of the population frequently exposed to occupational ionizing radiation. Widespread radiation exposure in the human medical profession has been minimized by specialization, but most veterinary physicians remain generalists.

The objective of our study was to assess the use of radiation safety features and the observance of state regulations in a sample of veterinary practices.

Materials and Methods

The sampling frame consisted of the 87 veterinary practices in Central Ohio having radiograph machines registered with the Radiologic Health Unit of the Ohio Department of Health. Central Ohio was defined as Franklin, Delaware, Licking, Fairfield, Pickaway, Madison, and Union Counties.

The sample size was calculated at 29 to estimate the proportion of the practices in which employees used protective equipment,[3] with an accuracy of ± 15 percent and a 95 percent confidence interval. The sample size was increased by six to compensate for potential refusals. This sample of 35 practices was chosen using computer-generated random numbers.

A letter was sent to the owners of all 35 sampled practices during July 1987. Consent was sought in a telephone interview the following week. The owners of 29 practices agreed to participate. Three owners refused to allow a site visit, another one was ineligible because the practice had been sold, and the final two were unreachable after numerous attempts over a two-week period.

The site visits were conducted during the last three weeks of August 1987. The first part of each visit consisted of a face-to-face interview about practice characteristics, personnel, and procedures used for taking radiographs. Next, a site evaluation was conducted looking at equipment, personal protection devices, and the posting of safety notices. A copy of the site visit results was left with each practice at the conclusion of the visit. The results of the site visits and interviews were analyzed descriptively.

Results

The radiation safety procedures used in the practices are summarized in Table 1. Although lead aprons and gloves were available in most of the practices, gloves were not always worn. The available aprons and gloves had been tested for leaks in only seven practices. Additionally, radiation safety training had been conducted in only 10 practices. Among the 16 practices in which film badges were worn, badges were shared by several individuals in three practices.

Collimators to narrow the x-ray beam and reduce the scatter radiation were used in 25 practices; diaphragms were used in three practices and cones were still in use at the one remaining practice. Diaphragms and cones are older methods of collimation that are no longer considered adequate to reduce scatter radiation. Techniques charts (to limit overexposure as a result of poor quality radiographs) listing the peak kilovoltage, the milliamperage, and the time of exposure necessary for taking all radiographs were available in 26 practices. Intensifying screens, which reduce the amount of exposure necessary to produce a radiograph, were available in all 29 practices. The walls and doors were lead-lined in the room containing the radiograph machine in just two practices, and in only five practices was a lead shield available for the employees to stand behind.

Three types of safety notices (the safe operating procedure, the machine registration, and a "Notice to Employees") are required to be posted near the radiograph machine according to the Ohio Administrative Code. The required safe operating procedure, which includes guidelines for taking radiographs and procedures for resolving questions and problems, was written for only eight practices. In only three practices was the safe operating procedure posted. The machine registration was posted in eight practices and the "Notice to Employees" was posted in five practices. All

TABLE 1—Summary of Radiation Safety Procedures Used in 29 Veterinary Practices in Central Ohio

Safety Procedure	% Used
Lead aprons and gloves worn	96.6
Film badges worn	55.2
Radiation safety training	34.5
Safe operating procedure written	27.6
Apron and gloves tested for leaks	24.1
Protective thyroid collars worn	0.0
Lead glasses worn	0.0

three of the required documents were posted in only three practices; none were posted in 18 practices.

Discussion

Veterinarians come in contact with many potentially harmful substances through their work. In this study and in a companion study,* exposure to ionizing radiation did not appear to be one of the most pressing concerns for many of the veterinarians. As suggested in similar studies completed in the 1950s,[4,5] the small number of radiographs taken may account for the minimal exposure found in the companion study* rather than good protective techniques. In our study the amount of radiation protection available in the sampled practices appears to have been minimal.

Lead shields, protective thyroid collars, and lead glasses are examples of established protective equipment not frequently observed in this study. Additionally, lead-lined walls and doors in the room containing the radiograph machine would help reduce the exposure of employees working elsewhere in the facility.

Veterinarians need to strive for exposures as low as reasonably achievable (ALARA), a concept first proposed by the National Committee on Radiation Protection in 1954. This is an extremely important concept since it is generally believed that there is no threshold value for exposure to ionizing radiation. To attain this goal, protective equipment needs to be made available, maintained in good condition, and used properly and routinely. Additionally, the importance of adequate radiation protection should be continuously re-emphasized by veterinary professional organizations and colleges of veterinary medicine. Finally, regulatory agencies in each state need to ensure that all established guidelines for minimizing occupational exposure to ionizing radiation are publicized and enforced.

New Rule Governs Graduate Fellowships for Nursing School Faculty

A rule governing grants for postbaccalaureate fellowships for nursing school faculty was proposed in the June 5 *Federal Register* by the Health Resources and Services Administration of the US Public Health Service.

Approximately 1,440 public or private nonprofit schools of nursing would be eligible to apply for grants to enable nursing faculty to:

- Investigate cost-effective alternatives to traditional health care modalities with special attention to the needs of at-risk populations;
- Examine nursing interventions that result in positive health status outcomes, particularly with regard to family violence, drug and alcohol abuse, women's health, adolescent care, and disease prevention; or
- Address other nursing practice areas considered by the HHS secretary to require additional study.

To be eligible for fellowship support under the proposal, a faculty member must expect to meet requirements for a master's or doctoral degree before the end of the grant's budget period and be conducting a substantial study, thesis, or dissertation in a specified area. The rule proposes that grants would be awarded first to support applications demonstrating special factors related to national needs, as announced in the *Federal Register*. Approximately $1.1 million was appropriated for the postbaccalaureate faculty fellowship program in fiscal 1989.

Mortality among Children and Youth

Lois A. Fingerhut, MA, and Joel C. Kleinman, PhD

Introduction

Substantial decreases in the mortality of children and youth in the United States have been observed since 1900. While decreases in mortality occurred from birth to old age, children have experienced the largest declines. However, a recent National Center for Health Statistics (NCHS) report shows that despite the successes that have been achieved, there still remain appreciable age, race, and sex differences in the amount of the decline and in the current (1983–85) status of the mortality of children and youth.[1]

The large proportion of deaths from external causes—injuries, homicide and suicide (ICD codes E800–E978)—distinguishes mortality at ages 1–19 from mortality at other ages. In the early 1930s, less than one-fourth of all deaths in this age group were associated with external causes; by 1983–85, one-half of all deaths (ages 1–19) were due to injuries with an additional 14 percent attributed to homicide and suicide. Three in 10 deaths were caused by motor vehicle injuries, a proportion far greater than that for any other single cause of death in this age group.

All of the US mortality data in this report are for the 50 States and the District of Columbia and are based on data from death certificates provided by State and city vital statistics offices to the National Center for Health Statistics (NCHS) (or to its predecessor agencies). Data for eight other industrialized nations are also included, based on tabulations provided by the World Health Organization, individual country reports, and selected detailed studies.

Trends

The first half of the 20th century witnessed very large declines in mortality, especially among the youngest children, ages 1–4 and 5–9. From 1900–50, the death rate declined by about 90 percent in each of these age groups to 139 per 100,000 children ages 1–4 and to 62 per 100,000 children ages 5–9. From 1950–85, these large declines continued, reaching 51 per 100,000 among children ages 1–4 and 25 per 100,000 in children ages 5–9. Declines in mortality for children ages 10–14 and 15–19 were around 80 percent during the first half of the century. For children ages 10–14 the decline also continued—falling 50 percent during 1950–85 to 28 per 100,000 children. Among teenagers 15–19, the total decline since 1950 has been only about 25 percent; the death rate in 1985 (81 per 100,000) was only about 10 percent lower than it was during the early 1960s (Figure 1).

In 1900, external causes of death were responsible for about 10 percent of the deaths of children and youth. By 1950, however, the proportions were much higher, ranging from 27 percent at ages 1–4 to 48 percent at ages 10–19. In 1985, external causes comprised 64 percent of all such deaths with proportions ranging from 45 percent among preschoolers ages 1–4 to 78 percent among teenagers 15–19.

Current Status, 1983–85

In 1983–85, the death rate of Black children ages 1–4 was 70 percent higher than that of White children; for Black children ages 5–9 the rate was 50 percent higher. External causes of death accounted for half of the race difference in death rates for children 1–4 years of age and three-fourths of the difference for those ages 5–9 years. In particular, three causes of death (fires, homicide, and pedestrian-related motor vehicle injuries) accounted for about 45 percent of the excess deaths among Black children ages 1–4 and 65 percent of the excess among Black children ages 5–9 (Figure 2).

At ages 10–14 years, the Black-White mortality ratio decreased to 1.3 and among teenagers 15–19 the death rates for Whites and Blacks were essentially the same, a feature unique to this age group. However, there were extremely large racial differences in the causes of death for teenagers

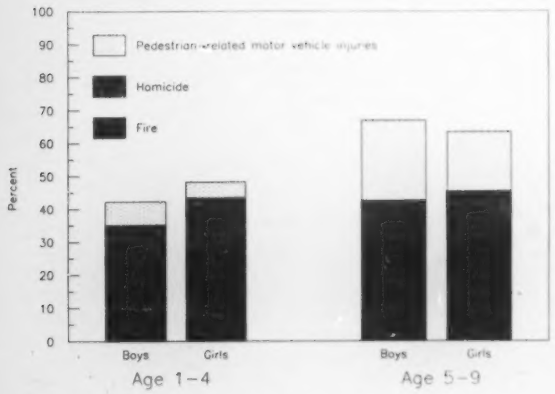

FIGURE 2—Percent of Excess Black Deaths Attributable to Specific Causes, 1983–85

15–19. The homicide rate for Blacks was five times that for Whites while the motor vehicle injury death rate for Whites was nearly three times that for Blacks.

Cross-National Comparisons, 1985

Childhood mortality in the US is generally higher than mortality in eight other industrialized nations.[2–5] However, death rates for natural causes showed little cross-national variation; natural-cause death rates in the United States generally ranked mid-way among the rates in the eight comparison countries (Table 1). Malignant neoplasms and congenital anomalies were the leading natural causes of death among children in the United States and in all of the other countries.

In contrast, US death rates for external causes ranked highest or second highest among these countries (Table 1). The causes of fatal injuries in European countries and other developed nations were similar to those in the United States—motor vehicle injuries and drownings. However, injury death rates were substantially higher in the United States, Canada, and Australia than in most of the other comparison countries. Generally, the US death rates were 1.5–2.0 times the rates in the five European countries.

Suicide rates among 15–19-year-old males varied widely in 1985, from a low of 4.3 per 100,000 in England and Wales to 18.4 in Canada. The US rate was 16.0. Among females, the rates were much lower, ranging from 1.1 in England and Wales to 5.3 in Sweden. The US rate was 3.7.

Homicide rates among 15–19-year-olds reveal a very different picture. In the United States, the rate was 13.2 per 100,000 for males, nearly five times higher than the rate in Canada and Australia and about 20 times higher than in the European countries. The excess homicide mortality in the United States is evident for both White and Black males. The homicide rate for US White males ages 15–19 (7.3 deaths per 100,000 population 15–19) was 3–24 times higher than the rates in the other countries and the rate for US Black males (46.4) was 17–155 times higher. The cross-national differences were smaller among females, but the US rates were by far the highest.[3–5]

In the United States, 74 percent of the 1,223 deaths from homicide among 15–19-year-old males (69 percent among Whites and 80 percent among Blacks) were caused by firearms (ICD code E965). Among the comparison countries, only in France did the proportion approach this level, at 12 out of 18 deaths. Forty-two percent of the homicide deaths in Canada and 31 percent of those in the Federal Republic of Germany were caused by firearms. None of the homicide deaths in Japan, England and Wales, or in Sweden were caused by firearms (Table 2). For females in the United States, 45 percent of the 356 homicide deaths were firearm-related (44 percent among Whites and 48 percent among Blacks). Similar to males, the number of these deaths in the other countries was extremely small. (Data were not readily available for Australia or The Netherlands.)

Final 1986 Mortality Data

Canada	26	11	15	5
Japan	14	0	14	1

*In the US, homicide generally includes "legal intervention" (ICD codes E970–E978). In 1985, there were 22 deaths among males and one death among females, thus bringing the total number of homicide deaths to 1,602.
SOURCE: Data are from the 1985 annual vital statistics reports of each listed country.

press, the 1986 mortality data were not yet available. With their current availability,[6] it is worth noting that, in general, childhood and youth mortality did not change much between 1985 and 1986. However, there are specific changes that merit careful attention:

Homicide Mortality

While homicide has been the leading cause of death among Black males ages 15–19, the death rate had been declining during the years 1980 through 1984. In 1985, the rate increased from 39.3 to 46.4 per 100,000; and in 1986 the increase continued to 51.5. Thus, there was a 31 percent increase in two years.

Motor Vehicle Injury

Motor vehicle injury is the leading cause of death among White males ages 15–19. From 1981 to 1985, the death rate had declined an average of 5 percent per year. In 1986, however, the death rate increased 13 percent to 58.4, higher than it had been since 1981. Motor vehicle injury mortality increased for each of the three other race-sex groups as well. Among Black males, for whom this is the second leading cause of death, the rate increased slightly from 21.2 in 1984 to 21.9 in 1985; and in 1986 the rate increased 17 percent to 25.6, to the level it had been in the late 1970s.

Injury prevention in childhood has been targeted by the US Public Health Service as a priority concern.[7] Given the far lower death rates observed elsewhere in the world, the goals for reducing mortality from injuries, homicide, and suicide would seem to be achievable.

Journal of Mental Health Administration Invites Submission of Manuscripts

The *Journal of Mental Health Administration* (JMHA), official publication of the Association of Mental Health Administrators, is seeking manuscripts on new developments, innovations, and trends in the management of mental health, substance abuse, and related behavioral health and disability programs. JMHA also publishes articles on mental health planning, policy analysis, marketing, law, financing, organizational structure, program evaluation, and the entire spectrum of mental health management and service delivery issues.

Contributions (typed double-spaced) are invited in the form of regular articles (16 pages), commentaries (12 pages), brief reports (5 pages), and letters to the editor (2 pages). To be considered for publication, papers should be mailed to:

Health Promotion Programs

a low-cost resource from the publishers of the nation's leading patient education materials.

Qualifying health professionals may choose programs developed specifically for use by health educators:

- Child nutrition & feeding
- Pediatric obesity
- Adult obesity
- Smoking cessation
- Personal fitness
- Stress management
- Pulmonary disease

Each package program includes:

- Instructor video training
- Instructor's Guide
- Patient Education Workbooks
- Program Promotion Materials
- Comprehensive Support Services
- Continuing Education

All at special, low prices to health educators.

Model Standards Impact on Local Health Department Performance in California

CAROL SPAIN, MPH, EILEEN EASTMAN, MA, AND KENNETH W. KIZER, MD, MPH

Abstract: An evaluation of a state-local negotiation process to implement Model Standards in 18 California local health departments was conducted during 1985–87. Model Standards specific to California were developed by state and local public health officials for seven programs. Nine counties participated in state-local negotiations to set performance standards in these seven programs.

During the two-year effort, greater use of Model Standards and more improvement in local program performance occurred in local health departments that participated in the state-local negotiation process. The use of Model Standards appeared to contribute to establishing program priorities, emphasizing the measurement of outcomes, improving data management systems, and evaluating the current performance of programs. While this state-local negotiation process is suggested as the preferred approach to encouraging the use of Model Standards in local health departments, it must be recognized that this process requires time and commitment of resources from both the state and local levels. (*Am J Public Health* 1989; 79:969–974.)

Introduction

Experience utilizing the Model Standards has substantially increased since 1979, when their use began as a collaborative effort among the US Conference of City Health Officers, the National Association of County Health Officials, the Association of State and Territorial Health Officials, the American Public Health Association (APHA), and the federal Centers for Disease Control (CDC).[1] Beginning with the publication of *Model Standards for Community Preventive Health Services*, a number of reports have described uses for or experience with public health standards in general and with Model Standards in particular.[2–9]

Three major approaches have been used to implement the Model Standards process, each requiring different levels of administrative sponsorship: 1) statewide projects that have had strong state health department sponsorship; 2) local health department actions without state sponsorship; and 3) individual efforts by local program managers without strong local or state health department sponsorship. The relative effectiveness of the different levels of sponsorship has not been determined. However, the APHA and CDC are currently conducting a Model Standards Technical Assistance Project which is supporting and documenting the progress made in 13 local and state Model Standards projects.[10]

Two evaluations of the use of Model Standards have been conducted in California.[11,12] The California approach to implementing Model Standards has involved the use of a state-local negotiation process to set local Model Standards objectives. On reporting the first project results, Weiler stated, "Project findings suggest that the Model Standards negotiations could provide state and local levels of government with a valuable tool for determining health care priorities and generating objective programmatic data for budget justification." The strength of the project was determined to be the negotiation process itself, but both state and local program managers felt that the initial limited evaluation period did not allow for adequate assessment of the results of the process.

This report describes the results of more extensive efforts to assess the impact of Model Standards implementation in California. Specifically, this evaluation looked at five areas: 1) setting of objectives via a state-local negotiation process; 2) achievement of objectives and improvement in program performance; 3) impact of data availability and improvements in data collection; 4) administrative evaluation of the Model Standards process; and 5) key determinants to successful application of Model Standards.

Methods

There were two major components of this effort: 1) the specification of Model Standards specific to California, and 2) a comparison of the impact of state-local negotiations over the two-year observation period, January 1985 through December 1986. California-specific Model Standards were established for seven programs: Chronic Disease Control, Sexually Transmitted Disease (STD) Control, Tuberculosis Control, Food Protection, Nutritional Services, Vehicular Injury Control, and Non-Vehicular Injury Control. Eighteen counties participated, representing the demographic and geographic diversity of the State. The Health Officers Association of California (HOAC), a private nonprofit membership organization of California's local health officials, was the independent organizational subcontractor charged with observing and evaluating the project.

Standards Specification

The first component of this project involved the specification of Model Standards for the seven programs noted above. A goal statement, outcome and process objectives, and key data indicators were specified for each of the seven programs. A total of 94 objectives were specified. The document used as the basis for this specification was the first edition of *Model Standards*.[1] Committees comprised of both state and local program managers and health officers met over a three-month period to develop these standards, which were approved by the California Conference of Local Health Officers in April 1984.

Selection of Counties

California has 61 local health departments (56 single county health departments, one bi-county health department,

Address reprint requests to Carol Spain, MPH, Public and Environmental Health Divisions Administrator, Public Health Division, Contra Costa County Health Services Department, 1111 Ward Street, Martinez, CA 94553. At the time of the study, she was Deputy Director for Planning and Program Administration, Health Officers Association of California, Sacramento. Ms. Eastman is Executive Secretary, California Conference of Local Health Officers, California Department of Health Services; Dr. Kizer is Director, California Department of Health Services. This paper, submitted to the Journal November 3, 1987, was revised and accepted for publication March 28, 1989.

Editor's Note: See also related editorial p 967 this issue.

© 1989 American Journal of Public Health 0090-0036/89$1.50

and four city health departments). State law delegates significant authority to the local level, while retaining broad state enforcement powers and considerable public health activity at the state level. Local health officers have a strong working relationship with the California Department of Health Services and are statutorily represented by the California Conference of Local Health Officers (CCLHO). HOAC conducts public health legislative, research, and educational activities.

Eighteen county health departments participated in this project; nine of them participated in negotiations with the State. All were selected because of their willingness to participate as *either* a "negotiating" or "nonnegotiating" county and their fitness to be paired with a comparable county for evaluative purposes. To select pairs representative of the State, a number of variables were identified as important selection criteria, and counties were paired according to these attributes (See Appendix).

Setting of Objectives

Prior to the beginning of each of the two observation years, all 18 counties completed an assessment document that included the California-specific Model Standards for the seven programs in the project. Each program standard contained a goal statement followed by a series of program objectives. For each program objective the following questions were asked:

- What is the current status of the objective?
- When can the objective be achieved?
- To what degree can the objective be achieved within the next year?
- How can achievement of the objective be measured or demonstrated?

In addition, State Health Department staff in the seven programs used the same assessment documents to assess the project counties from the State's perspective.

Negotiations were then undertaken with nine counties. Completion of the negotiation process for all seven programs required two days, with each program negotiation session lasting approximately two hours. Participants in each negotiation session generally included the local health officer, local program manager, state program representative, a facilitator, and an observer. Usually, the state and local program representatives were the same individuals responsible for completing the assessment documents. Negotiations were on-site in the local jurisdiction so that local staff participation could be maximized. In all, 125 separate negotiation sessions were conducted during the two years, one at the beginning of each year in each of the nine counties.

In the nine counties not participating in the state-local negotiation process, program objectives were set by the local health department.

Local Implementation and Evaluation

Progress toward achieving the objectives set was evaluated at the end of each of the two years by means of on-site interviews and mailed questionnaires. Data were gathered to document changes in program performance, staff, funding, and data management.

Improvement in individual program performance was one of the key outcomes evaluated. Improvements in program performance were equated with setting and achieving program objectives (both process and outcome) at higher levels of performance than the baseline performance of the program as determined by the state and local health departments. Improvements in program performance were also self-reported in general by program managers and, if related to the use of Model Standards, were noted as such. No external measurement of program performance or improvement in program outcomes was conducted.

Results

Setting of Objectives and State/Local Negotiations

Ninety-four objectives covering all seven program areas were specified at the onset of the project so that, in the aggregate, a total of 1,692 objectives (846 each year) could have been set for both the negotiating and nonnegotiating health departments. During the two-year assessment, negotiating health departments set a total of 1,160 objectives, and nonnegotiating health departments set 830 objectives. A drop in target objectives occurred in the second year, with nonnegotiating health departments decreasing the number of objectives by 70 percent (637 to 193) and negotiating health departments by only 10 percent (611 to 549).

Negotiating health departments specified an increased level of performance in 725 objectives over two years, while this occurred for only 223 objectives in nonnegotiating health departments (Table 1).

In both groups, medium- and small-sized counties set their objectives at higher levels of performance most frequently. The specific programs in the second year that set objectives at higher performance levels most frequently were Non-Vehicular Injury Control (62 percent), Nutrition Services (62 percent), and Chronic Disease Control (60 percent). These programs generally had not achieved high levels of program performance prior to the study and had many objectives yet to achieve.

In both years, negotiating health department staff rated the state-local negotiation process as the most useful aspect of the project. Eighty-two percent of the programs reported staff benefits from negotiations, and 79 percent of the programs reported that state-local negotiations had a positive impact on program performance.

Achievement of Objectives and Improvements in Program Performance

As shown in Table 2, both negotiating and nonnegotiating departments achieved similar proportions of the objectives they had set but negotiating departments achieved 507 objectives and their counterparts only 177. Control of Sexually Transmitted Diseases and Vehicular Injury were the programs for which both sets of health departments reported the most objectives achieved.

The programs whose improvements in program performance were considered by both groups as due to the use of Model Standards were Tuberculosis Control (61 percent), STD Control (61 percent), and Nutrition Services (50 percent). Negotiating health departments reported that these programs also received significant technical assistance from state staff as a by-product of the negotiation process.

Negotiating health departments reported that Model Standards assisted in improving program performance in 40 of 63 programs, in contrast to 15 to 63 programs in nonnegotiating health departments. Programs that had a program organizational unit (e.g., Tuberculosis Control) and those that had state funding reported this impact most frequently. Thirty-two programs in both groups reported staff increases during the two-year study and 11 of these reported that the increases were due in part to the use of Model Standards. These staff increases were achieved primarily through inter-

TABLE 1—Setting of Objectives[a]

	Negotiating Health Departments		Nonnegotiating Health Departments
	Prior to Negotiation	Post Negotiation	
Year 1			
Health department agrees to increase its level of performance	19% (N = 97)	72% (N = 440)	19% (N = 121)
Health department agrees to do the same as or less than the previous year[b]	81% (N = 411)	28% (N = 171)	81% (N = 516)
Totals	N = 508	N = 611	N = 637
Year 2			
Health department agrees to increase its level of performance	36% (N = 141)	53% (N = 285)	52% (N = 102)
Health department agrees to do the same as or less than the previous year[b]	64% (N = 250)	48% (N = 264)	47% (N = 91)
Totals	N = 391	N = 549	N = 193

[a]There was a total of 94 objectives specified for the seven program areas. Thus the total possible number of objectives was 846 per year for each set of health departments (negotiating and nonnegotiating).
[b]Objectives that were set at "maintenance of effort or less" levels were considered "pre-achieved."

TABLE 2—Achievement of Objectives[a]

	Number of Objectives		
	Objectives Achieved[a]	Objectives Not Achieved	TOTAL
Year 1			
Negotiating	65% (N = 282)	35% (N = 152)	100% (N = 434)
Nonnegotiating	59% (N = 71)	41% (N = 49)	100% (N = 120)
Totals	63% (N = 353)	37% (N = 207)	100% (N = 560)
Year 2			
Negotiating	64% (N = 225)	36% (N = 182)	100% (N = 507)
Nonnegotiating	63% (N = 106)	37% (N = 63)	100% (N = 169)
Totals	63% (N = 431)	36% (N = 245)	100% (N = 676)

[a]This refers to objectives set at higher performance levels and objectives set at the same level (maintenance) but achieved at a higher level.

nal redirections in response to the commitment to achieve a higher level of performance.

Impact of Data Availability and Improvements in Data Collection

Overall, 15 of the 18 health departments reported that data availability was an important consideration in their decision to set specific Model Standards objectives. TB and STD Control programs had the most readily available data. In contrast, the setting of objectives for Non-Vehicular Injury Control and Chronic Disease Control was hindered by the paucity of data to measure outcomes.

Eight of the nine negotiating health departments reported that Model Standards had a positive impact on data management, in contrast to four of the nonnegotiating health departments. Most data improvements were in large county health departments, and ranged from gathering new primary data (e.g., smoking prevalence among pregnant women) to automating existing data systems. Data-related factors that contributed to the successful use of Model Standards included:

- knowledge about data sources that already existed;
- commitment to allocate staff time to analyze existing data;
- Ideas generated by local staff about additional existing data sources and types of new primary data that could be easily collected;
- capacity to automate the local health department data system; and
- knowledge and experience of local program managers in using outcome data in program planning and evaluation.

Administrative Evaluation of the Model Standards Process

Model Standards were used primarily by negotiating counties as an administrative tool to increase program accountability and responsibility for achieving objectives; to improve evaluation of current program effectiveness and efficiency; to measure results (outcomes); to enhance communication between program managers and their staff; and to provide an opportunity for staff to participate in decisions that directly affect their work. Other uses included improving communication between the local and state health department and generally improving the state-local relationship. Major barriers to the use of Model Standards reported from both sets of counties were lack of staff, lack of program priority status within the health department, and lack of data.

Ongoing Use of Model Standards

Two of the major indicators of the usefulness of Model Standards are the degree to which the negotiating health departments have integrated Model Standards into ongoing planning and evaluation documents and activities and their intention to continue to use Model Standards. In both areas negotiating health departments responded more positively than nonnegotiating health departments. For example, only one of nine nonnegotiating counties reported integration of Model Standards, while five of nine negotiating health departments reported such integration. Only eight of 63 programs in nonnegotiating health departments intended to use Model Standards in the future, in contrast to 30 programs in negotiating counties.

Key Determinants to the Successful Application of Model Standards

Several local factors determined the success of using Model Standards in local health departments. These included:

- *Strong Local Health Officer and Program Manager Commitment.* Commitment to use Model Standards by the health officer was rated as extremely important to the successful use of Model Standards by most participants. In counties where the program manager was very involved, both in completing the assessment and in participating in the state-local negotiations, Model Standards were observed to be more useful and there were more improvements noted in program performance and data management.
- *The Priority Status of the Program within the Local Health Department.* The seven programs in which Model Standards were used were pre-selected by the State Health Department based on criteria set by CDC in their proposal guidelines. The same set of programs was used in all 18 counties. In order to be most successful, however, it appears as though local health departments should select their own priority programs to which they apply the Model Standards. For example, many local health departments felt that Chronic Disease Control and Injury Control were not their highest priorities, and they set fewer objectives in these areas.
- *Availability of Data to Set and Measure Objectives.* Health departments that were unable to gather baseline and program activity data had the most difficulty with setting and measuring objectives because they had neither reference points nor a way to measure achievement. This seems to be an area that must be effectively addressed at both state and local levels if Model Standards are to be used effectively.
- *Relationship of Model Standards to Existing Planning and Evaluation Tools.* Many local health departments were setting program process objectives and linking their program plans to state and local funding before the publication of the first edition of *Model Standards*. From this assessment, it appears as though the most successful health departments have used the Model Standards as a more specific and technical guide for program objective setting and integrated their "new" program objectives (based on Model Standards) into required county or state mandated plans tied to local budgets and contract funding. In health departments where Model Standards were linked to existing planning requirements, program managers reported improvements in the presentation of their program plans and budgets and, in some cases, increased funding for programs.

Discussion

Overall, it appears that use of a state-local negotiation process results in greater use of Model Standards and more improvement in program performance by local health departments than in the absence of such a negotiation process. Negotiations provided a forum for state and local health department staff to come together, share data and program information, and set realistic and meaningful objectives. The negotiation process improved over time because of an observed "learning curve." Both state and local negotiators understood the scope of the objectives and the indicators that existed, or could be developed, to measure outcomes, and they were more skilled at representing their positions.

We believe it important that the first step in this negotiation process be a consensus conference or series of conferences at which state and local health officials reach agreement on state-specific Model Standards. The time and effort necessary to achieve this consensus should not be underestimated, and our experience indicates that this requires clear and vigorous sponsorship at both the state and local levels.

In our project, technical assistance given to the local health departments by the state negotiators was not tied to funding, contract negotiations, or contract monitoring and it was rated very highly by local participants—possibly due to this factor. The discussions between state and local participants during the negotiations seemed to help the local participants adapt the standards to their resources, programs, priorities, and data availability. Much of the technical assistance was simply a by-product of the negotiation process itself. Although negotiating health departments had the same concerns about their limitations in setting and achieving the objectives as nonnegotiating health departments, they often chose to set more objectives because the negotiation discussion helped to focus on what a local health department could do within a one-year period to achieve a particular objective.

Both state negotiators and negotiating local health departments rated the negotiation process highly. The state negotiators generally felt that the ability to offer broad programmatic assistance was stimulating to themselves and useful to local staff. They also achieved a greater understanding of local programs, a better idea of the types of state assistance needed by counties to set local standards, (e.g., data) and an appreciation for which local health departments needed technical assistance in the future.

There are a number of difficulties that are encountered when conducting an evaluative study such as this one, including difficulties in achieving a true "control." In reality, the interest of local health departments in participating in the study was a factor that had to be considered. Although more counties were interested than were paired and participated, those that participated, either in the negotiating or nonnegotiating groups, were interested in being exposed to the Model Standards process. The true controls, one could argue, were the county health departments that did not exhibit an interest in participating in the study. In addition, because there was no external measurement of program performance conducted in either group of counties, the achievement of objectives and assessment of improvements in program performance, staffing, and funding were self-reported. Some of the achievements were related to improved outcomes in individual programs (e.g., more individuals served; delivery of a new program component) and some were related to process achievements (e.g., number of objectives set; integration of Model Standards into planning efforts).

From our experience, we conclude that a state-local negotiation process does improve local health department program performance but requires time and commitment of resources from both state and local health departments. We also believe such a negotiation process is the preferred approach to encouraging the use of Model Standards by local health departments. However, to be meaningful and to optimally meet the needs of both local and state health departments, both the use of Model Standards and the negotiation process should be integrated into the state health department's local assistance activities and should relate to clear state health department goals and administrative support.

AIDS Triggers Increase in State Worker Notification Laws

Notifying workers of possible exposure to the acquired immunodeficiency syndrome (AIDS) virus has become an important focus of state legislative activity, according to a report published by the AIDS Policy Center of the Intergovernmental Health Policy Project. The report, based on a 50-state review of more than 100 worker notification laws enacted between 1983–88, found that, at the end of 1987, 16 states had laws on the books requiring that workers—primarily emergency medical technicians (EMTs) and funeral personnel—be notified if they were exposed to HIV (human immunodeficiency virus) or other diseases. By the end of 1988, the number had doubled. More than half of state worker notification laws mandate that both emergency care personnel and a variety of other workers, ranging from health care providers to corrections staff, be notified of actual or potential exposure to HIV.

Some laws define patient contact very broadly referring to "any contact," although more states now require that a worker must have "significant exposure"—i.e., direct contact and exchange of blood, needlesticks, and scalpel cuts—before notification will occur. Since 1988, state laws in 16 states define "significant exposure," compared to only three states before 1988.

The issue of testing following HIV exposure is a feature in a number of notification laws, although procedures regarding testing are not always outlined in these statutes. Notification leads to required testing in some states, usually of the patient to whom a worker was exposed. Patient informed consent is not always required, although 14 states now require or permit patients to be tested following worker exposure to HIV. Only six states (FL, LA, ME, RI, UT, WA) mandate patient informed consent before testing.

Few of the worker notification laws specify how the testing-after-exposure information is to be managed. A few states have levied penalties for breach of confidential information, including criminal penalties (AL, GA, IN, UT); licensure sanctions (ME, VA), dismissal from employment (IN).

Worker notification laws in 15 states require workers to be educated or trained in preventive procedures. Michigan holds employers liable in settings that have not developed and implemented policy guidelines for breaches of confidentiality of HIV-related information.

The External Costs of a Sedentary Life-style

EMMETT B. KEELER, PHD, WILLARD G. MANNING, PHD, JOSEPH P. NEWHOUSE, PHD, ELIZABETH M. SLOSS, PHD, AND JEFFREY WASSERMAN, MA

Abstract: Using data from the National Health Interview Survey and the RAND Health Insurance Experiment, we estimated the external costs (costs borne by others) of a sedentary life-style. External costs stem from additional payments received by sedentary individuals from collectively financed programs such as health insurance, sick-leave coverage, disability insurance, and group life insurance. Those with sedentary life-styles incur higher medical costs, but their life expectancy at age 20 is 10 months less so they collect less public and private pensions. The pension costs come late in life, as do some of the medical costs, and so the estimate of the external cost is sensitive to the discount rate used. At a 5 percent rate of discount, the lifetime subsidy from others to those with a sedentary life style is $1,900. Our estimate of the subsidy is also sensitive to the assumed effect of exercise on mortality. The subsidy is a rationale for public support of recreational facilities such as parks and swimming pools and employer support of programs to increase exercise. (*Am J Public Health* 1989; 79:975–981.)

Introduction

A growing body of literature indicates that regular exercise may prove beneficial in ameliorating the consequences or preventing the onset of a wide range of diseases and chronic conditions.[1–9] The consequent improvements in health may translate into decreased use of health services and increased job productivity, resulting in economic benefits to society at large. Conversely, those who choose to lead more sedentary lives may actually impose costs on others.

We term such costs—costs that others pay as a result of an individual's decision to lead a relatively inactive life rather than exercise—external costs. By contrast, internal costs are those borne by the individual and are presumably taken into account in decisions about how much to exercise. External costs stem from additional payments received by sedentary individuals from collectively financed programs such as health insurance, sick-leave coverage, disability insurance, and group life insurance. The premiums and payroll taxes that finance these programs are the same for sedentary and active individuals. As a result, these social welfare programs may have the unfortunate side effect of subsidizing unhealthy behavior.

The external costs of smoking and drinking can in principle be converted to internal costs by appropriate excise taxes, but it is difficult to imagine how to tax a sedentary life-style. If, however, a sedentary life-style does impose external costs, subsidies to facilities and programs that promote exercise could well save money in the long run. Such subsidies might take the form of public parks or other recreational facilities that charge no fee or have fees below cost. The greater the external costs of inactivity, the greater the possible value of exercise promotion. In order to shed further light on this issue, we have calculated the external costs of a sedentary life-style.

Our focus on external costs can be contrasted with a recent analysis of the total (internal and external) costs and benefits of exercise.[10] Under assumptions similar to ours, exercise was shown to improve health efficiently, especially for those who enjoyed exercising. That analysis should encourage people to exercise because it is good for them. In this paper, we study a different question, which is more relevant to government action—if someone exercises, is that good for other members of society?

Methods

We will briefly describe our methods and data; more details can be found in the Appendix and in a forthcoming report, available from the authors.*

Cost Analysis

We focused our cost analysis on the lifetime (as opposed to current) costs incurred by individuals who exercise to varying degrees because some of the effects of exercise persist for many years. In judging any policy with long-term effects, it is important to discount costs that are incurred in the future. Most analysts of health policies consider a 5 percent discount rate as standard, but because the proper rate of discount is controversial, we have computed results for several discount rates that span the range commonly used.[11]

In order to assess the costs associated with reduced physical activity, we made use of a hypothetical person: the "active inactive" individual. Because we were only interested in estimating the effects of exercise on external lifetime costs, we needed to hold constant the effects of other differences between those who do and do not exercise regularly; this we did by changing only the value of the exercise variable in our estimated regression equation. Thus, we use the "active inactive" individual to determine what the lifetime costs would be if the group of inactive people in our sample had instead been active throughout their lives but retained all of their other characteristics.

Our modeling approach involved tracking, from age 20 to death, hypothetical cohorts of sedentary men and women who, for the purposes of comparison, were counterfactually made physically active. To accomplish this, we developed a life table, based on exercise status, that showed the probability of surviving to each age (see Appendix).

We used the life tables to compute the difference in costs that are due to a lack of exercise. These expected net external lifetime costs, X, are given by the formula:

*Manning WG, Keeler EB, Newhouse JP, Sloss EM, Wasserman J: The external economic costs of poor health habits. Santa Monica, CA: The RAND Corporation, forthcoming.

$$X = \sum_{t=20}^{z} \delta^{t-20} \cdot P(A|S)_t \cdot C(S)_t$$

$$- \sum_{t=20}^{z} \delta^{t-20} \cdot P(A|RE)_t \cdot C(RE)_t$$

where

δ = annual discount factor ($= 1/(1 + r)$),
$P(A|S)_t$ = probability of surviving from 20 to at least age t given a sedentary life style,
$C(S)_t$ = annual costs minus taxes and premiums at age t for those who are sedentary,
$P(A|RE)_t$ = probability of surviving from 20 to at least age t given regular exercise
$C(RE)_t$ = annual costs minus taxes and premiums at age t for those who exercise regularly.

The lifetime external costs of leading a sedentary life included in our analysis are: covered medical costs, covered work loss, group life insurance, the widow's bonus in Social Security, covered nursing home costs, pensions, and disability insurance. (Covered means paid through a collectively financed public or private policy.) Because inactive people lead shorter lives, they will pay less of the taxes and premiums that finance these programs. This differential adds to the lifetime costs borne by active people and so must be included (see Appendix).

Although the cost analyses follow hypothetical cohorts over time, the information for what happens at each age is based on recent (cross-sectional) experience for that age, and not on projections of what life will be like, e.g., in the year 2048 when those 20 years old in 1988 turn 80. Thus, we did not estimate the effects of secular and biomedical trends on the sequalae of a sedentary life-style. Instead, we used current estimates for such parameters as retirement, medical and nursing home costs, education, and life insurance arrangement. This simplifying assumption is commonly made (e.g., by the National Center for Health Statistics[12] in computing life expectancy) because the alternative is too difficult and too conjectural.

Data

The primary data source for those under age 60 is the RAND Health Insurance Experiment (HIE), which has detailed information on health habits, diseases and chronic conditions, and the utilization of medical services. Because those aged 62 or over at the time of enrollment were excluded from the HIE sample and because we wanted to estimate lifetime costs, we used data on the elderly from a 1983 supplement to the National Health Interview Survey (NHIS) that includes information on health habits, use of medical services, and work loss. We supplemented these two sources with information from the Current Population Survey (CPS), the National Medical Care Utilization and Expenditure Survey (NMCUES), the Centers for Disease Control (CDC), and other sources.

The HIE sample is a random sample of individuals observed between November 1974 and January 1982 from six sites throughout the United States (Dayton, OH; Seattle, WA; Fitchburg, MA; Franklin, MA; Charleston, SC; and Georgetown, SC).[13,14] For this paper, we used data on 3,074 individuals enrolled in fee-for-service plans who were between the ages of 20 and 59. For those age 60 and over, we used unpublished data from the National Health Interview Survey (NHIS).[15] These data are from a supplemental questionnaire on health habits that was administered to 20 percent of the respondents to the 1983 NHIS who were at least 18 years of age; this yielded a sample of 22,418 persons.

Measures of External Costs

The costs of medical services are external to the degree they are financed by health insurance. We know the fraction of inpatient and outpatient expense paid out of pocket on average for each age, so it suffices to compute the effects of exercise on total medical spending. In our analysis, we examined differences in medical expenditures between those who engaged in regular exercise and those who did not. In the case of the HIE, medical expenditure measures were based on insurance claims filed during the experiment for periods up to five years; and in the case of the NHIS, on reported outpatient visits and hospital admissions in the preceding year.

The work loss measure used in the analysis for those under age 60 is based on responses to a health diary that was filled out biweekly by HIE participants. Work missed by those surveyed in the NHIS was estimated using responses to a question concerning the amount of work missed over a two-week period. Data on wages and pensions come from the Current Population Survey.[16,17]

Measures of Exercise Status

We classified each person in the HIE data set into one of the following three categories based on his or her reported level of exercise (ascertained by a single question) at the time of enrollment into the study: those with light or no exercise (mostly sitting or walking); moderate or strenuous exercise several times a week; or strenuous exercise most days. Individuals with role or physical limitations were separated from the rest of the population to avoid attributing the effects of their health problems to lack of exercise.

The exercise categories for the NHIS sample are also based on responses to a single question: "Are you less active, about as active, or more active than others your age?" Again, we placed individuals with physical or role limitations in a separate category. Thus, the NHIS categories differ from those of the HIE in that the NHIS measures each person's perceived amount of exercise relative to the average for his or her age group, rather than the more objective HIE measure of how often the person exercises.

Other Covariates

Our estimates of the effect of exercise on the costs of medical care and sick leave controlled for age, sex, race, smoking, drinking, education, health status, family income, and family size by including them as explanatory variables in a multiple regression analysis. In the analysis of the HIE data, we also controlled for coinsurance rate and the use of seatbelts. Education and seatbelt use are proxies for differences between those who engage in regular exercise and those who do not that may affect work loss and the use of medical services but are not affected by the amount of exercise.

Results

Use of Medical Services and Work Loss

Although moderate exercisers had 12 percent fewer outpatient episodes than the group with little or no exercise, strenuous exercisers had only 8 percent fewer outpatient episodes than those with little exercise (Table 1). The effect of strenuous exercise was substantially larger for inpatient use than for outpatient care (30 percent lower inpatient use

TABLE 1—Differences in Medical Use and Work Loss in the Health Insurance Experiment (HIE) Sample

Level of Exercise	Outpatient Episodes (excluding well-care)		Inpatient Admissions (excluding maternity)		Male Work Loss[a]	
	Ratio	95% CI	Ratio	95% CI	Ratio	95% CI
Little	100	—	100	—	100	—
Moderate	88	(80, 96)	90	(71, 113)	83	(61, 112)
Strenuous	92	(81, 105)	72	(52, 100.2)	68	(47, 99)

NOTE: Entry indicates percentage ratio of use to use by those with little exercise with similar non-exercise characteristics.
[a]HIE data did not permit an estimate of work loss for females.

rate compared to a 8 percent lower rate of use of outpatient care).

We were concerned that health status could affect exercise, as well as exercise affecting health status—the syndrome expressed by, "I exercise if I feel well." Even though we controlled for role or physical limitations, we felt that perhaps our dichotomous limitation measure was too crude a measure of ability to exercise. Hence, to check the sensitivity of our results to the possibility that health status may affect exercise, we added general health and mental health indices and a count of the number of chronic diseases to our list of covariates.[16] Strenuous exercisers had a 20 percent lower hospitalization rate and used 6 percent less outpatient care than light exercisers, after these adjustments (results not shown). Thus, the magnitude of the effect of exercise on inpatient use depends on how one treats the causal relationship between health status and exercise.

For adult males, moderate exercisers had 18 percent fewer work loss days than those with little exercise, while those with strenuous exercise missed 32 percent fewer days.

We also examined the effects of lack of exercise using the 1983 NHIS for all adults (Table 2). The NHIS sample exhibited a more pronounced effect of exercise than the HIE sample. As an example, for moderate exercisers, the HIE data exhibited a 12 percent lower outpatient use rate than for never or light exercisers, in comparison to the 29 percent lower outpatient use rate in the NHIS data for moderate exercisers.

Cost Analysis

As a base case, we estimated the external costs of those who, although not physically limited, do not exercise even when young—about 12 percent of men and 20 percent of women in our population. The lifetime external costs in each category for those who classified themselves as not very

active physically are given in Table 3. For those 20–59, we used data from the HIE and included all medical expenses (except maternity and well care) and all covered work loss; for the aged, we included all medical expenses based on data from the NHIS.

For undiscounted lifetime costs, medical costs and retirement pensions are the largest external costs, and after subtracting taxes on earnings, the total net undiscounted costs are $27,000 per person (Table 3).

Costs discounted at 5 percent show much lower nursing home and pension costs. The other costs fall less because a part of them occurs early in adulthood. The discounted lifetime external costs fall to $4,000 at a 5 percent discount rate, and $1,000 at a 10 percent rate.

Table 4 shows the change in these costs if relatively inactive individuals had exercised regularly but otherwise retained their characteristics and habits (i.e., if they became "active inactive" people). As discussed in the Appendix, we modify the CDC Health Risk Appraisal (HRA) estimates of the effects of exercise on men, and combine recent evidence[5,6,10] in assuming exercise adds 1.5 years of life for men. Then, additional exercise increases total life expectancy by 300 (undiscounted) days, and reduces medical costs. Because active individuals live longer, nursing home payments increase as do pensions. Overall, however, the effect of increased exercise is to decrease undiscounted external

costs.

The discounted external lifetime costs, which are more relevant to policy, tell a similar story. At a 5 percent discount rate, increasing exercise saves $1,900 in lifetime costs. This represents our best estimate of the external costs of a sedentary life-style. By way of comparison, at a discount rate of 5 percent lifetime external costs of relatively inactive persons are greater than those of smokers ($1,000), but less than those of heavy drinkers ($4,600).*

Sensitivity Analysis

We analyzed the influence of alternate assumptions concerning the effects of exercise on mortality (Table 5). For convenience, the first column of Table 5 repeats the results from the second column of Table 4. The second column gives the costs assuming exercise has no effect on mortality; that is, the standard United States life table is used for both groups. Only medical costs and sick leave differ, and these are both higher for sedentary people than they would be if these same people were active.

The last column is based on the unaltered HRA results which show enormous beneficial effects of exercise on mortality (see Appendix). The mortality changes strongly affect pensions and use of nursing home care. If lack of exercise has a large effect on mortality, sedentary individuals pay much more in Social Security taxes than they live to collect. Even when discounted at 5 percent, these late-life effects mean that those who do not exercise subsidize those who exercise: the external costs of inactivity decrease as the assumed beneficial effect of exercise on mortality increases.

Next, we investigated the sensitivity of our results to other assumptions and data sets, while holding the effect on life expectancy at its middle value of 1.5 years for men. For comparison, the first column in Table 6 repeats the first column of Table 5. First, to test the sensitivity to data source, we used parameters based entirely on NHIS data (for the young as well as the old) (column 2). The major change was that the estimated effects of exercise on medical costs were much larger, which caused the external costs of a sedentary life-style to double. However, the sick leave and nursing home estimates are consistent with the HIE results.

Second, to test the sensitivity to how we estimated the health effects of exercise, we contrasted sedentary individuals with current exercisers, rather than with the sedentary people made hypothetically active (third column of Table 6). Because inactive people have other characteristics which are associated with lower medical use (for example they have less education, on average), they spend less on medical services than active people, despite their inactivity. The negative signs in the third column show that currently inactive people are not subsidized by exercisers; the first column however shows that inactivity is subsidized. In other words, if the people who are inactive started to exercise, they would pay current exercisers $1,900 more than the $700 they currently pay. The main reason inactive people do not impose higher external costs is that they die earlier.

The base case included all medical use, but some of the difference in medical use between inactive persons and "active inactive" persons may be unrelated to exercise. As a sensitivity test, we therefore narrowed the definition of medical services to those thought to be related to exercise and other habits. The fourth column gives the resulting medical costs when this restriction is imposed. (Here, we returned to the inactive group made hypothetically active.) Medical and total external costs fall by roughly a factor of two.

Fourth, many people become less active later in life. We therefore tried to estimate the costs that such a switch to inactivity impose on others. In doing so, we assumed that these people were similar to moderate or heavy exercisers up to age 50 and then became sedentary. Because the differences

TABLE 6—Sensitivity of Costs to Assumptions at 5 Per Cent Discount Rate

	Alternative Assumptions					
	Inactive Individuals if Active	All NHIS Data	Active Individuals	Narrow Definition of Medical Costs[b]	Switch at age 50	Total Costs
Costs[a]						
Medical costs[c]	1.8	4.4	−0.4	0.9	1.1	2.6

[d]Earnings, not taxes on earnings.

due to a sedentary life-style start late in life, sick leave and medical costs effects are diluted by discounting (column 5). At a 5 percent discount rate, external costs are $800 larger than if this group exercised throughout their lifetime.

Finally, the last column in Table 6 gives data on total costs rather than external costs; that is, it includes the portion borne by the person. Total costs are by definition higher than external costs in areas in which people pay part of the costs themselves. The costs shown in the last column amount to $4,000 but that figure does not count the cost to the sedentary person and his or her family of premature death and disability. Although this latter cost is probably larger than any of the costs shown, it is hard to quantify, so we have left the total cost figure in the lower right hand corner as a question.

Discussion

Because there has been no direct trial of the lifetime costs of not exercising, we have had to use several observational studies to estimate the components of costs. The main uncertainty in our overall estimate of lifetime costs comes from the validity of the assumptions, rather than statistical noise. Therefore, we have included extensive sensitivity analyses that show how our computed costs vary with the assumptions.

If sedentary individuals were more active they would live longer and reduce the costs they impose on others. The reduced costs come from lower covered medical and work loss costs associated with an active life-style. The higher taxes paid by active individuals over their longer lifetimes more than offset the additional pension payments received by active people as a result of their increased life expectancy. The effect of exercise is appreciable; for example, the external costs of a sedentary life-style are almost double the external costs of smoking.

In contrast to drunken drivers, the costs that sedentary people impose on others are indirect; sedentary people do not drive their armchairs into innocent bystanders. Most of these external costs are captured in the model, but we assumed there were no effects of inactivity on early retirement. In a study of those obtaining permanent disability Social Security benefits in 1975, 38 percent of retiring workers ages 55–64 had cardiovascular disease as their primary diagnosis.[19] Assuming the year 1975 was typical, we can estimate that three per cent of those ages 55–64 retire early because of cardiovascular disease, to which lack of exercise can contribute. Early retirement has large external costs associated with it, both because it decreases taxes paid and increases pension and disability insurance payments. If a sedentary life-style increased the probability of early retirement, our estimates of the external costs of a sedentary life-style are too low.

One of the largest uncertainties in our calculations concerns the degree of causality in the link between exercise and health status. Although we controlled for physical limitation and several other differences between exercisers and non-exercisers, we cannot be certain that the association we have found between inactivity and health-related costs is completely causal. In principle, this issue could be settled by a randomized experiment of the effects of exercise promotion, but size, cost, ethics, and long-term adherence problems make such an experiment impractical. The issue of causality remains to plague any observational attempt to estimate external costs of inactivity.

The association between exercise and mortality raises the same chicken-and-egg issue. Many epidemiological studies have shown dramatic differences in future heart disease between those who are sedentary and those who exercise.[5,6,20] These studies have controlled for age and other health habits. Still, it is hard to rule out the possibility that heavy exercisers are inherently more healthy than sedentary people in unmeasured ways, so that inactive persons who take up exercise will not enjoy the gains in life expectancy that models based on those studies would predict. If exercising has no effect on mortality and morbidity, then there are no benefits to making sedentary people more active. Because of this uncertainty, the revised HRA model 3.0 says only that exercise is probably good for you, and does not attempt to quantify its life-extending benefits.

Nevertheless, individuals contemplating a switch to a more active life-style will probably benefit from doing so.[5] According to Paffenbarger and Hyde,[4] the time spent walking is just returned in later life (undiscounted), and joggers who burn calories twice as fast as walkers can get double their exercise time back in increased life expectancy. However, the time given up to exercise is now, while the life extending benefits of exercise accrue in the future. Hence, if people care more about time now than time later,[11] they should engage in exercise that they either enjoy or has other benefits for them (e.g., increasing their feeling of well-being, physical appearance, etc.).

From a policy perspective, our results provide an economic rationale both for government spending on recreational facilities that encourage a more active life style, as well as for employer spending on worksite wellness programs that encourage exercise. About one-sixth of the population is sedentary but not physically limited. Whether subsidies to encourage exercise would induce enough additional exercise among that group to justify their costs is an issue we must leave to others; if our estimate of $1,900 in benefits per active person is approximately correct, a relatively small additional percentage of exercising would be enough to justify a subsidy, especially because the majority who already exercise would also derive benefits from such facilities and programs.

ACKNOWLEDGMENTS

This work was financed by a Grant No. HS05278-02 from the National Center for Health Statistics Research (NCHSR), Rockville, Maryland. An early version of this paper was presented at the APHA meetings in New Orleans in the fall of 1987. Some of the results have been discussed in seminars at the University of California-Los Angeles and at NCHSR.

APPENDIX
Further Details of Methods

1. Basis of Life Tables

We constructed an abridged life table using 1980 data on national mortality and the 1984 Centers for Disease Control's version of the Health Risk Appraisal (HRA) program developed by Robbins and Hall.[21] The HRA was used to adjust survival rates to reflect differences in the relative risks of dying between people who exercise and those who lead more sedentary lives.

Unfortunately, some problems in the 1984 HRA model's treatment of exercise lead to implausibly large estimates of the effects of exercise. For example, according to computations that we performed using the HRA model, men who switch from a sedentary life style to exercise will live nine years longer, almost double the computed effects of not smoking! This estimate is implausibly large for two reasons: 1) the HRA fails to account for the fact that better health may lead one to exercise, rather than vice versa; and 2) the adjustment made to the HRA model's exercise risk multipliers for age is inadequate, which makes the computed effects of exercise for older males too large. These two problems were compounded by the fact that our measures of exercise do not match well with the HRA categories. For example, because we had no information on past exercise habits, we had to assume that current patterns represent lifelong patterns. Yet exercise habits are not particularly stable.

Given these problems, we decided to estimate the external costs of exercise in three ways. As an upper bound on mortality effects, we used the unaltered results of the HRA model. For a lower bound, we assumed that exercise had no effect on mortality whatsoever, so that external costs arose only from differences in medical and sick-leave costs for sedentary and active people. For our best estimate, we uniformly altered the age-specific relative mortality risks of not exercising in the HRA model, so that male exercisers lived one and a half years more than male nonexercisers. This value was derived from several recent studies.[5,6,10] We did not adjust the mortality values for women because very little is known quantitatively about the effects of exercise on women and because the effects of exercise in the HRA model were not nearly as large as for men.

2. Assumptions on Collective Financing

To simplify the calculation of how much active and inactive people pay annually to finance these programs, we assume that each pays a given proportion of earnings, where the proportion is just enough to finance these programs (10.3 percent of earnings, at a 5 percent rate of discount). The assumption of proportionality is approximately correct for publicly financed goods and services,[22] and is also probably correct for privately financed pensions. Private premiums for health insurance are regressive, but this is somewhat offset by the benefits of Social Security payments and Medicaid financing for nursing home services being progressive.

3. Medical Care Services and Insurance Coverage

We examined the use of medical care services (excluding dental care) by those who exercise varying amounts. In the case of the HIE (RAND Health Insurance Experiment), medical expenditure measures were based on claims filed during the experiment for periods up to five years, and the individual's pre-experimental insurance coverage was used to estimate external costs. In the case of the NHIS (National Health Interview Survey), medical measures were outpatient visits and hospital admissions in the preceding year. Visits and admissions were converted to expenditures using average prices from the National Medical Care Expenditure Survey (NMCES),[23,24] and data on insurance coverage of the non-elderly from NMCES were used to estimate the portion of medical costs that were external.

In our analysis, we examined differences in medical use between those who engaged in regular exercise and those who did not. Because some of the observed differences in medical care use may not be caused by the amount one exercises, we made three corrections:

- We excluded maternity services because it seemed implausible that exercise was causally related to the decision to have children. (We also excluded well care because it is generally not covered by insurance.)
- To increase the chances that the difference in use of medical services is caused by differences in the

amount one exercises, we limited one set of analyses to diagnoses thought to be directly related to bad habits.
- We controlled for a set of confounding variables, as described in the text.

4. Work Loss

In the HIE, work loss includes time lost from work due to one's own or someone else's illness, including time for visits to a physician. A half-day or more missed from work was counted as a work-loss day. Because we do not know the reason for the work loss, we cannot restrict our measure to sick days due to illnesses known to be related to exercise. Instead, we estimated the difference in total work loss among persons with different levels of exercise, controlling for health habits and other covariates.

Wage data from the CPS were used to convert work loss days into costs. To obtain a figure for external costs, we used an estimate that employers pay 38 percent of the cost of work loss.[25]

5. Comparison of the HIE and NHIS Data Sets

We compared the estimated effects of exercise on medical costs and work loss on the non-elderly in the NHIS and the HIE data. Although there were few statistically significant differences, in some cases there were appreciable differences in the estimated coefficients. The differences in the magnitude of the estimated responses to exercise between the HIE and NHIS prompted us to perform the cost analysis two ways: 1) we used data from the HIE for those under age 60 and the NHIS for those 60 and older; 2) we used data exclusively from the NHIS (i.e., for all age groups).

6. Wages and Pensions

Data on wages come from the Current Population Survey.[16] Data on pensions, public and private, by age, sex, and education class also come from the Current Population Survey; they have been adjusted for the estimated 21 percent underreporting factor in this survey.[17] (We include private pensions as collectively financed because most are defined benefit plans rather than defined contribution plans and because defined contribution plans generally convert to annuities whose payout is independent of exercise status.) We assume survivors in each age, sex, and education class get the average pension for that class, i.e., we assume amount of exercise has no effect on age at retirement.

Cancer Prevention Fellowship Program Invites Applications

The Division of Cancer Prevention and Control (DCPC) is accepting applications for the Cancer Prevention Fellowship Program (CPFP). The purpose of the program is to attract individuals from a multiplicity of health science disciplines into the field of cancer prevention and control. The program provides for:

- Participation in the DCPC Cancer Prevention and Control Academic Course;
- Working at NCI directly within individual preceptors on cancer prevention and control projects;
- Brief field assignments in cancer prevention and control programs at other institutions.

Funding permitting, ten Fellows will be accepted for up to three years of training, beginning July 1, 1990. Benefits include selected relocation and travel expenses, paid federal holidays, and participatory health insurance.

Eligibility for the program is restricted to the following categories:

- MD or DO degree from a US, territorial, or Canadian Medical School, or
- PhD, DrPH, or other doctoral degree in a related discipline (epidemiology, biostatistics, and the biomedical, nutritional, public health, or behavioral sciences), or
- Foreign education, comparable to that received in accredited US, territorial or Canadian institutions. Foreign medical graduates must have current ECFMG/FMGEMS certification and appropriate experience, e.g., one year residency in a training program approved by the Accreditation Council for Graduate Medical Education.
- US citizenship or resident alien eligible for citizenship within four years.

The deadline for receipt of applications is September 8, 1989. To receive further details and application packet, sent a *postcard* with your name and home address to: Douglas L. Weed, MD, MPH, PhD, Cancer Prevention Fellowship Program, Division of Cancer Prevention and Control, National Cancer Institute, Executive Plaza South, T-41, Bethesda, MD 20892. Further inquiries: Mrs. Barbara Redding (301) 496-8640 or 496-8641.

Multivariate Prediction of Total and Cardiovascular Mortality in an Obese Polynesian Population

DOUGLAS E. CREWS, PHD

Abstract: The effects of body weight and blood pressure on the risk of total mortality and mortality from cardiovascular diseases (CVD) were examined in a prospective sample of 5,866 adult residents of American Samoa, a Polynesian population noted for exhibiting high levels of obesity. Data collected during 1975–76 were linked to mortality records from 1976 through 1981. In logistic regression models which did not include blood pressure, percent of desirable weight was an important risk factor for mortality from CVD, but it was not an important risk factor when diastolic blood pressure was included in the model. Percent of desirable weight was not related to mortality from all causes combined in either Samoan men or women. Age and diastolic blood pressure were predictors of total and CVD mortality in men and women.

These results, in an obese population, suggest that body weight and obesity are not independently related to excess mortality in the very obese, although they may associate with high blood pressure. These results also suggest that relations between physiological characteristics and mortality may vary with cultural, genetic, or other factors not examined in this study. (*Am J Public Health* 1989; 79:982–986.)

Introduction

The Medico-Actuarial Mortality Investigation of 1912[1] showed an increasing probability of death with increasing levels of body weight or blood pressure. Evidence that elevated blood pressure leads to early mortality, particularly mortality from cardiovascular diseases (CVD), has continued to accumulate,[2–6] but the influence of overweight and obesity on total and CVD mortality has been questioned.[6–12] At a recent National Institutes of Health (NIH) Consensus Development Conference on the Health Implications of Obesity,[13] most participants supported the view that obesity was predictive of early mortality, particularly from the vascular diseases,[14–16] but at least two papers reported some results that were counter to prevailing opinions.[9,17]

Age, weight, blood pressure, and fatness are generally accepted as risk factors for early mortality in western industrialized populations.[2–5,12,18–24] Although most prospective studies have assessed these relations in Western or White populations, data from the Honolulu Heart Program suggested that such associations also occur in Japanese Americans.[25]

Several genetically and culturally distinct populations reside on islands of the South Pacific. Of these, American Samoans are particularly noted for their heavy body weights, overt obesity, and hypertension.[26–30] Furthermore, this mainly Polynesian population exhibits high mortality rates from CVD and diabetes mellitus.[28,31]

As part of a longitudinal research program to examine the health consequences of modernization on American Samoans,[32] a prospective investigation was conducted of the relations between age, body weight, and blood pressure, and six-year mortality from all causes and from cardiovascular diseases (CVD). Multivariate analyses are reported here; univariate associations have been reported elsewhere.[33]

Methods

Study Sample

American Samoa is a group of high volcanic islands, lying in the South Pacific about 15° below the equator and just east of the international dateline. Tutuila, the main island, upon which over 90 percent of the population of American Samoa resides, comprises a total land area of less than 76 square miles. In 1974, 67 percent of adult males and 37 percent of adult females were employed and earning weekly wages,[34] with the remainder generally engaged in traditional subsistence and household activities.

Since 1962, the LBJ Tropical Medical Center has been a major provider of health care in the islands and has housed the registration office for vital statistics. The medical center also houses the Public Health Department which maintains nurses in clinics throughout the islands. In general, the nurses are familiar with the health problems of all households in the villages for which they are responsible.[35] Since almost all births and deaths are reported to either the outlying public health clinics or the medical center, there is little opportunity for incomplete ascertainment of vital events.[36]

Risk Factors

During 1975 and 1976, members of the Pennsylvania State University Samoan Studies Project (SSP)[32] and the Department of Public Health of American Samoa collected data on age, height, weight, systolic (SBP) and diastolic blood pressures (DBP) on 2,704 men and 3,162 women ages 20 to 90 years residing in 52 different American Samoan villages located on Tutuila. Percent of desirable weight was computed as weight (kg)/Metropolitan Life Insurance desirable weight specific for sex and height.[7,8] Percent of desirable weight was interpreted as an index of obesity.

All risk factors were measured according to standardized techniques.[30,37] However, some digit preference in blood pressure measurements has been previously noted in the Department of Public Health sample.[38] Methods and techniques of data collection and descriptions of the data have been presented elsewhere.[28,30,32,38,39]

Characteristics of the Sample

Summary statistics for survivors, all decedents, and those who died of CVD are presented in Table 1. The average age of the women sampled was 43 years, while the men averaged 44 years. In general men and women weighed the same; but men were approximately 10 cm taller. Thus, body mass index (BMI, computed as weight (kg)/height(m)^2) was higher in women. For comparison to published height and weight data from United States samples,[7] this sample of

[a]CVD = Cardiovascular diseases

Samoan women averaged 5'3" in height and weighed 187.0 lbs, while the Samoan men averaged 5'7" and weighed 191.8 lbs. Among Samoan women and men these weights were, respectively, 35–41 percent and 27 percent above the midpoints of optimal weights for height recommended in the 1959 Metropolitan Life Insurance Height/Weight Tables and the Gerontology Research Center 1985 Weight for Height tables.[7] Neither SBP nor DBP showed sex-related differences.

The total sample represented approximately 59 percent of the Tutuila population aged 20 years or more in 1974. The age distribution of the sample was not significantly different from that of the 1974 census population.[38] The presence of cardiovascular and other diseases was not determined at baseline; nor were adequate data available to control for smoking habits, both possible confounders of the weight-mortality relationship.

Mortality Data

In general, death certification in American Samoa follows the pattern commonly used in the United States.[36] During January 1982 all official death records registered with the Department of Vital Statistics at the LBJ Tropical Medical Center between January 1, 1976 and December 31, 1981 were microfilmed. In 1972, death registration in American Samoa was reported to be nearly 100 percent complete.[36] Even if a few migrants were missed, previous research suggests they probably differed little in mean blood pressures (BP) from the residents.[29,30]

Underlying causes of death were categorized following protocols described in the 9th revision of the International Classification of Diseases, Injuries and Causes of Death (ICD-9).[40] The mortality data were then linked to the previously described survey data using the name, age, sex, and village of residence data from the death certificates. One hundred seventy-one decedents, 113 men and 58 women, were identified. Of these, 42 men and 21 women had died of CVD, (ICD-9 codes 401-459). The 2,591 men and 3,104 women for whom no death record was found provided the survivor sample. Previous estimates suggested 88 percent complete ascertainment of six-year decedents.[33]

Statistical Methods

Unadjusted associations of the risk factors with mortality were reviewed. The relative risk of mortality by categories of Metropolitan Life Insurance desirable weights,[5] and by quartiles of DBP, adjusted for age and sex, were estimated using multiple logistic regression.[41,42] Because few deaths occurred in the lowest two quartiles of DBP, they were combined to provide the base category for the analysis of mortality. Models with multiple predictor variables were used to estimate independent effects of percent of desirable weight and DBP on mortality controlling for age. Body weight unadjusted for height was not included in the logistic models. BMI and SBP were dropped because percent of desirable weight and DBP provided better fits to the mortality data. Risk functions including two factor interactions and quadratic effects were estimated. None of the age or weight by blood pressure interactions or quadratic terms was statistically significant; these exploratory analyses have been presented elsewhere.[28,39]

Four terms from each logistic model were presented, the estimated coefficient relating each risk factor to the endpoint along with its standard error (SE), the estimated relative risk (RR) of dying associated with a 10-year increase in age, a 10 mmHg increase in DBP, or a 10 percent increase in desirable weight, and a 95% confidence interval (95% CI) for the estimated RR.

Results

At their initial examinations in 1976, men and women who subsequently died within six years were 14.6 and 14.0 years older than those who survived (Table 1), for CVD deaths men were 18.9 years older, but women were only 12.7 years older than survivors. Absolute body weight, BMI, and percent of desirable weight were slightly but not significantly higher among men who subsequently died or died of CVD than they were among six-year survivors (Table 1). Samoan women showed higher levels of obesity and lower ages at death than did men. Both SBP and DBP were higher at baseline among Samoans who died than among those who survived six years. Men and women who survived showed similar blood pressure levels. However, among both total and CVD decedents, women showed higher SBP and DBP than men. Age-adjustment did not substantially alter any of these relations.

The relative risks (RR) of mortality from CVD and from all causes, adjusted for age and sex, according to desirable

weight levels are shown in Table 2. The pattern of estimated relative risks suggests a U-shaped function for mortality from cardiovascular diseases and all causes, with a graded relationship of increasing risk at each level of desirable weight above the 90–109 percent class. For the markedly overweight, percent desirable weight greater than or equal 160 percent, the RR of mortality from CVD was three times that of the 90–109 percent group. Despite this, when the 54 individuals with percent of desirable weight below 90 percent were deleted and the logistic function was used to test for a trend of increasing mortality with higher ranks of desirable weight, controlling for age and sex, no statistically significant trend was evident by the chi-square test.

Table 2 also presents relative risks according to quartiles of DBP. The RR of mortality from CVD and all causes combined increased with higher quartiles of DBP.

To distinguish the effects of DBP and weight seen in Table 2, logistic regression models were fitted for total and CVD mortality by sex. These models included age, DBP, and percent of desirable weight. The 54 individuals for whom percent of desirable weight was less than 90 percent were excluded from these analyses. Age and DBP were independent predictors of mortality from all causes in both Samoan men and women, but percent of desirable weight was not an independent predictor (Table 3); an increase of 10 percentage points in desirable weight was associated with a relative risk of only 1.04. Among Samoan women, a 10-year increase in age yielded a relative risk of death of 2.08, somewhat less than for men. Conversely, a 10 mmHg increase in DBP was associated with a 46 percent increase in the risk of death among Samoan women, twice the increase associated with DBP among Samoan men.

Age and DBP significantly increased the risk of six-year mortality from CVD among both Samoan men and women. Percent of desirable weight showed a weak positive association with risk in men and a weak negative association in women when the effect of DBP was also considered. Among Samoan men, age and DBP more strongly influenced the risk of mortality from CVD than the risk of mortality from all causes. Similarly, the coefficient for percent of desirable weight was higher for CVD than for death from all causes, among men. Among Samoan women age influenced mortality from CVD less than it did mortality from all causes combined, but DBP more strongly associated with the risk of CVD death.

Discussion

At a recent NIH Consensus Development Conference on the Health Implications of Obesity,[13] Garrison and Castelli[15] reported that 26-year mortality was lowest among Framingham men classified into the 100–110 percent group of the 1959 Build and Blood Pressure Study's desirable weight ranges. In this study of Samoans the lowest risk of mortality, especially from CVD, occurred in a similar category of relative weight, those 90–109 percent of Metropolitan desirable weights. The trend toward higher risks of mortality from all causes and CVD at both higher and lower percents of desirable weight suggested the now familiar U-shaped risk function. With individuals below 90 percent of desirable weight excluded from the analysis a trend of increasing mortality across the upper four categories of desirable weight was evident but not statistically significant in this sample. Estimates from a multiple logistic risk function suggest that elevated body weight and obesity are risk factors for total and CVD mortality in the extremely obese, but that this is secondary to the association of obesity with high blood pressure.

A strength of the study was the large and complete sample of the adult population of Tutuila. Therefore, the weak effect of body weight on mortality, adjusting for blood pressure, is probably not an artifact of the sampling design.

The average BMI in this Samoan sample was significantly above levels related to increased mortality in United States samples,[33,45] as was the average percent of desirable weight. Thus, the average Samoan man or woman in this study may have been above some critical threshold, after which the cardiovascular sequelae of obesity no longer increased. Although this suggestion may appear to contradict the finding that above 160 percent of desirable weight, excess CVD mortality was observed (Table 2), the effects of BP were not accounted for and both sexes were combined due to small numbers of observed deaths. Furthermore, at such extreme levels of body weight, mechanical and other unmeasured concomitants of extreme body weight may have contributed to the observed association.

A second possibility is that a six-year follow-up was too short a time period for the cardiovascular sequelae of obesity to be fully expressed. In the Framingham study the relation between relative body weight and mortality was weaker during the first 12 years of follow-up than during the second 12-year period,[45] however other studies with follow-up

TABLE 2—Relative Risk of Death, Adjusted for Age and Sex, from all Causes and Cardiovascular Diseases among American Samoans According to 1959 Metropolitan Life Insurance Desirable Weights and Quartiles of Diastolic Blood Pressure (DBP), Determined Using Logistic Regression[a]

lengths similar to this one have reported significant associations between obesity and mortality.[46]

Third, it is possible that the obese in Samoa were younger than in other populations, and as a consequence this population has not yet experienced the cardiovascular sequelae of their obesity. Negative correlations which existed between body weight or BMI and age[28,33] suggest this may be the case. An earlier analysis implied that overweight may influence mortality outcomes among younger Samoans.[47] Thus, as younger cohorts age the cardiovascular sequelae of their obesity may become more pronounced.

Several risk factors not included in this study, such as smoking and alcohol consumption or diet, may be confounding factors in the obesity mortality relationship in Samoans. Recently, Lew[16] reiterated the need to control such confounding factors before determining the effect of weight on mortality. Additional data to control for smoking habits might have helped explain part of the U-shaped relation between obesity and mortality and may have increased the relative risks reported for percent of desirable weight in the logistic analysis. However, the relative risks among Samoan women, who were a good deal more obese than men and seldom smoked cigarettes, were well below unity, suggesting that addition of a smoking variable may have had little effect.

Many studies have reported no association between body weight and mortality. Keys' review of 13 prospective studies found that only one showed a definite univariate relationship between overweight and CHD.[43] Similarly, review of 16 prospective studies of obesity and mortality led Andres to conclude that obesity does not influence total mortality the way one would expect.[33] What the present study indicates, as Barrett-Connor suggested based on a number of previous studies of well-defined populations,[9] is that it is often difficult to find a relation between body weight and increased mortality in populations unselected for risk factor status. This is particularly true in studies of nonwestern, nonindustrialized populations, and holds for mortality from all causes and CVD.[9,11,17,32,33,43,44] This suggests that at least two additional factors previously suggested by Stallones,[17] different research methods and true differences between the study populations, may have influenced these results. These two factors may also have interacted to accentuate differences between studies in Samoa and the United States.

The sample used in this study was composed mainly of Polynesian residents of American Samoa. They have a common genetic and cultural heritage, which is not the same as that of populations studied in the United States. It is possible that population heterogeneity has been a major difference between studies reporting a body weight-mortality relationship and those reporting none. Thus, differences in research samples, rather than designs may explain some observed differences in risk factor associations.

There also may be true differences between populations in the relation between body weight and mortality. These differences may stem from genetic factors relating to energy metabolism, storage, or expenditure and may have both an evolutionary and ecological explanation. It may also be that specific mechanisms have evolved in certain populations, such as the Polynesians of the South Pacific, so that they tolerate larger amounts of body fat without experiencing cardiovascular problems. In this context it may be rewarding to think in terms of a "thrifty genotype" as suggested by Neel.[48]

Given the extreme body sizes of present-day Samoans, it is easy to suggest that this population has an exaggerated ability to process food energy into fat. Such a physiological mechanism may also have conferred some degree of protection from the cardiovascular responses commonly observed in populations with greater genetic diversity and a different evolutionary history. This is similar to Alexander's suggestion that extreme obesity may carry some protective effect against the development of coronary heart disease.[49]

ACKNOWLEDGMENTS

The author wishes to express his appreciation to the staff and administration of the LBJ Tropical Medical Center in Fagotoga, American Samoa, to all the Samoans who participated in the health surveys, and to C.M. McCuddin of the American Samoan Health Planning Council. I also wish to thank Drs. P.T. Baker, T.S. Baker, J. Mitchell, and A.R. Dyer, and Ms. L. Neville who read drafts of this manuscript. Portions of this research were presented at the 1984 and 1985 scientific meetings of the American Association of Physical Anthropologists. This research was partially supported by an NIA predoctoral fellowship in interdisciplinary gerontology (NIA Grant No. 5-T32-A600048-07), an NIA postdoctoral fellowship in the demography of aging (NIA Grant No. 1-T32-A600116-01), the Evan Pugh research fund of the Pennsylvania State University, and NIGMS Grant No. 5-T01-GMO-1748 to Dr. P.T. Baker.

APHA Epidemiology Section to Sponsor 'Late-Breaker' Poster Session

The Epidemiology Section of the American Public Health Association has issued a call for abstracts of papers suitable to feature in their "Late-Breaker" Poster Session, to be held during the upcoming APHA meeting in Chicago. The session will take place on Wednesday, October 25, 12:30–2:00pm. Work completed in 1989 is eligible for consideration.

Abstracts must be received by September 11, 1989 to be considered. Students and recent graduates are particularly encouraged to submit their work for this session. Abstracts should be less than 200 words; any format is acceptable. Enclose a self-addressed postpaid envelope to expedite the response from the program planner. Contact:

Necrotizing Enterocolitis Mortality in the United States, 1979–85

ROBERT C. HOLMAN, MS, JEANETTE K. STEHR-GREEN, MD, AND MICHAEL T. ZELASKY, BS

Abstract: The Multiple Cause of Death Mortality data from the National Center for Health Statistics were analyzed to describe epidemiologic characteristics and trends in deaths related to necrotizing enterocolitis (NEC) among infants in the United States from 1979 to 1985. The average annual mortality rate (multiple cause mortality) for NEC was 13.1 deaths per 100,000 live births. NEC annual mortality rates decreased significantly during the study period for White and Black infants, male and female infants, and infants in the Northeast, North Central, and South regions. Black infants were approximately three times more likely to die from NEC than White infants, and the NEC infant mortality rate was highest in the South. (*Am J Public Health* 1989; 79:987–989.)

Introduction

Necrotizing enterocolitis (NEC) is a serious gastrointestinal tract disorder in newborns,[1–3] affecting predominantly premature or low-birthweight infants. The overall incidence is approximately 1 to 3 cases per 1,000 live births[3–8] and 1.0 percent to 7.7 percent of all admissions to neonatal intensive care units.[1,9–12] Death associated with NEC results from intestinal perforation with sepsis, disseminated intravascular coagulation, and short bowel syndrome following intestinal resection.[1,13] Case series suggest that NEC mortality rates may be as high as 56 percent; however, rates have varied by study[1,8,14] and may have decreased over time.[14–16]

Before 1979, the International Classification of Diseases (ICD) did not provide unique coding for NEC as a cause of death. With the adoption of the ninth revision of the International Classification of Diseases in 1979, a cause-of-death code (777.5) was made available specifically for NEC. This provision allowed for the differentiation of NEC from gastroenteritis and colitis as a cause of death in death certificate data. In this study we analyzed NEC-related deaths in the United States from 1979 to 1985 for epidemiologic characteristics and mortality trends.

Methods

Multiple Cause of Death Mortality data for the United States from 1979 to 1985 were obtained from the National Center for Health Statistics (NCHS).[17] Cause-of-death classifications by NCHS from death certification data used the Ninth Revision of the International Classification of Diseases (ICD-9).[18,19] NEC deaths were considered those in which ICD-9 code 777.5 appeared in any one of 20 record axis codes,[17,18,20] i.e., deaths in which NEC was recorded as any one of the multiple causes of death. The record axis coding is a method which links causes of death into categories for certification by NCHS, and lists up to 20 causes of death for an individual.[20] The record axis data classification is comparable to the underlying cause classification, since it uses the same rules and category definitions.[17,20] However, the multiple cause of death data allows for mortality statistics based on a number of different causes reported on the death certificate.[20,21] Israel, *et al*, discussed the usefulness and limitations of multiple cause data in detail.[21]

The multiple cause of death data enabled us to examine NEC as an important factor in death. The NEC deaths included infants who died within the first year of life, plus two infants with unknown age. Detailed natality public use tapes from NCHS were used to determine the number of live births in each subgroup annually from 1979 through 1985.[22,23] All rates in this study represent multiple cause mortality rates, unless otherwise specified.

Annual NEC infant mortality rates based on multiple cause were calculated as the number of NEC deaths per 100,000 live births. The overall rate (multiple cause) for the study period (1979–1985) was calculated as the total NEC deaths per 100,000 live births during the study period. The overall and annual mortality rates were calculated for the United States and by race, sex, and region. Relative risks (RR) with 95 percent confidence intervals (CI) were calculated to compare specific mortality rates.[24] Linear regression analysis by the unweighted least squares method was used to describe the relationship of mortality rates to time.[25]

To examine racial differences and trends, race was categorized as White, Black, and other races. Geographic differences and trends were analyzed by standard census regions—Northeast, North Central, West, and South.

Results

From 1979 to 1985, 3,327 NEC deaths in infants were reported in United States multiple cause data, an average mortality rate of 13.1 deaths/100,000 live births per year (Table 1). Of these deaths, 79.6 percent were reported as the underlying cause of death, yielding an average underlying cause of death rate of 10.4 deaths/100,000 live births per year. During this period, NEC represented 1.1 percent of all infant mortality. Eighty-seven percent of NEC deaths occurred within the first month of life. The annual NEC mortality rate for the United States decreased significantly over time, from

TABLE 1—NEC Mortality Rate by Region and Race, United States, 1979–85

Region	Total (N)*	Race		Black/White RR (95% CI)
		White (N)	Black (N)	
Northeast	13.3 (628)	10.4 (402)	29.8 (218)	2.9 (2.4,3.4)
North Central	10.9 (707)	8.0 (441)	31.1 (258)	3.9 (3.4,4.5)
South	16.4 (1433)	10.3 (662)	35.0 (761)	3.4 (3.1,3.7)
West	10.0 (559)	9.0 (414)	26.0 (104)	2.9 (3.2,3.7)
United States	13.1 (3327)	9.4 (1919)	32.4 (1341)	3.4 (3.2,3.7)

Holman, MS, Chief, Statistics and Data Management Activity, Division of Host Factors, CID, CDC, Bldg. 1, Rm. 1332, Mailstop D02, Atlanta, GA 30333. Dr. Stehr-Green is medical epidemiologist, and Mr. Zelasky is statistician, with the Division. This paper, submitted to the Journal October 18, 1988, was revised and accepted for publication January 27, 1989.

14.5 deaths/100,000 in 1979 to 10.2 deaths/100,000 live births in 1985 (regression coefficient (b) and standard error = −0.75 (.12), R^2 = .88), a 29.7 percent overall decrease (Figure 1).

Overall, the NEC mortality rate for Blacks (32.4 deaths/100,000 live births) was significantly higher than for Whites (9.4 deaths/100,000 live births) (Table 1). The rate for other races (6.9 deaths/100,000 live births) was significantly lower than for Whites (RR = 0.7; 95% CI = 0.6, 0.9). For each year NEC mortality rates for Blacks were significantly greater than for Whites (Figure 1); however, relative risks remained similar over time. Annual rates declined significantly over time both for Blacks (28.3 percent) and Whites (31.1 percent) (Black, b = −1.58 (.54), R^2 = .56; White, b = −0.61 (.08), R^2 = .91).

The overall NEC mortality rate for males was higher than that for females (RR = 1.2; 95% CI = 1.1, 1.3) (Table 2). Annual rates declined significantly for both males (32.5 percent) and females (25.8 percent) (male, b = −0.74 (.22), R^2 = .70; female, b = −0.76 (.16), R^2 = .83). Both for males and females, the rate was significantly higher in Blacks than in Whites (Table 2).

The South had a significantly higher overall NEC mortality rate than the other three regions, and the West had a significantly lower rate than the Northeast (Table 1). The overall rate was significantly higher for Blacks than for Whites in all regions (Table 1). Among Blacks, the overall rate was highest in the South (35.0/100,000 live births); among Whites, the overall rate was highest in the Northeast (10.4/per 100,000 live births), and in the South (10.3/100,000 live births). Regression analysis showed a decrease in the rate from 1979 to 1985 in all regions (Northeast, b = −1.07 (.31), R^2 = .70; North Central, b = −0.75 (.15), R^2 = .84; South, b = −0.83 (.27), R^2 = .65; and West, b = −0.38 (.28), R^2 = .27) (Figure 2). The rate decreased over time both for Blacks and for Whites.

The overall rate for males was slightly higher than for females in all regions. Among males and females alike, the rate was lowest in the West, and highest in the South.* Among males, the rate was significantly higher in the South than in the North Central and West.

TABLE 2—NEC Mortality Rate by Sex and Race, United States, 1979–85

Sex	Total	Race		Black/White Relative Risk (95% CI)
		White	Black	
Male	14.3	10.6	34.5	3.3 (3.0,3.5)
Female	11.7	8.1	30.3	3.7 (3.4,4.1)
Total	13.1	9.4	32.4	3.4 (3.2,3.7)

Discussion

Our data corroborate the improvement in NEC mortality rates reported by others.[14–16] Potential causes for the decrease in NEC-related deaths include:

- a decrease in infants at risk for NEC because of improved prenatal care and a decrease in incidence of low birthweight and prematurity;
- a decrease in incidence of NEC among infants at risk because of prophylactic treatment (i.e., prophylactic antibiotics, parenteral nutrition, and/or IgA-IgG feeding);[26] and
- a decrease in mortality in infants with NEC because of earlier diagnosis, treatment, and surgical intervention.

The first two of these possibilities seem unlikely. Although there have been slow and recent declines in infant mortality,[27,28] including low-birthweight infant mortality, a parallel decrease in the proportion of low-birthweight infants has not been seen.[27] Also, although no data on the incidence of NEC are available during the study period, Finer, *et al*, and Kleigman, *et al*, reported an increase in incidence of NEC in the late 1970s.[9,10,28] Perhaps improvements in neonatal care, such as the institution of protocols discussed by Vermeylen, *et al*,[16] have allowed more premature infants to survive to develop NEC.

In our study, Black infants had more than a threefold higher risk of dying from NEC than White infants; this relative risk was consistent throughout the study period and by sex. Wilson, *et al*, reported a higher incidence of NEC in Black infants than White infants and a higher incidence in low-birthweight infants than in other infants.[4] After controlling for birthweight, however, the incidence and case fatality ratios did not differ between Blacks and Whites.[4] Kleinman, *et al*, also reported a higher incidence of low-birthweight

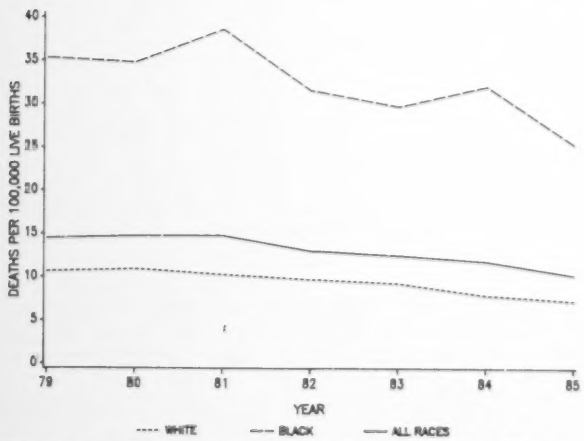

FIGURE 1—Annual NEC Mortality Rates by Race, United States, 1979–85

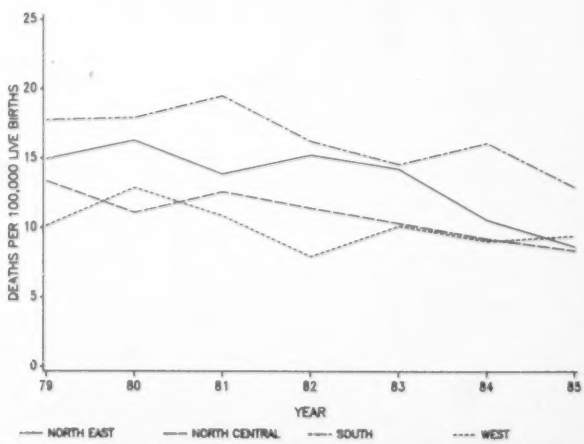

FIGURE 2—Annual NEC Mortality Rates by Region, United States, 1979–85

infants among Blacks.[29,30] During the 1970s, the incidence of low birthweight in Black infants in the United States was between two and three times higher than among Whites.[29,30] In 1980, the relative risk for low-birthweight Blacks was still greater than 2.0.[27] Therefore, the difference between Blacks and Whites in this study could reflect from an increased incidence of low-birthweight infants among Black infants. However, due to the limitation of the national mortality data, low-birthweight cannot be examined as an associated factor.

The sex differences that we observed in NEC rates have not been reported in previous case studies and are difficult to explain.[6,7,15] Male infants experience higher birthweight-specific infant mortality than female infants, regardless of race.[27] It is possible that the sex difference seen in NEC mortality can be attributed to the sex difference in overall infant mortality.

Infants in the South had a higher risk of NEC mortality than infants in the other three regions. In part this results from the higher proportion of Blacks in the South and the higher NEC mortality rate among Blacks. However, Blacks in the South had a higher mortality rate than Blacks in other regions. Blacks in the South do not have a higher incidence of low-birthweight births than Blacks in other regions.[31] The higher incidence of mortality due to NEC in southern Blacks may reflect less adequate postnatal care. However, there could be regional differences in the reporting of NEC. The use of standard cause-of-death classification does not assure strict comparability by region, which occurs only if all records of cause of death are reported with equal accuracy and completeness.[18] Since the reliability and accuracy is governed by the ability of the certifier, regional differences may reflect variations in reporting.[18,21,32]

Using national mortality data did not allow us to associate mortality with specific risk factors, such as birthweight, gestational age, clinical status at diagnosis, treatment, and maternal factors. NCHS will make available an annual national linked birth-infant death file for 1983–86.[33] Further studies will be able to expand upon our findings by examining the linked birth-infant death file for the United States with respect to the above risk factors, and should provide important information for the reduction of NEC mortality.

Population-Based Study of Unintentional Injury Incidence and Impact during Childhood

FREDERICK P. RIVARA, MD, MPH, NED CALONGE, MD, MPH, AND ROBERT S. THOMPSON, MD

Abstract: We report a prospective study of medically treated unintentional injuries ascertained in an HMO population of children and adolescents 19 years of age and younger over a one-year period. The overall rate of medically treated injuries was 247 per 1,000, 147/1,000 for those treated in the clinic, and 100/1,000 for those treated in the emergency room (ER). Overall, 2.5 percent of patients were hospitalized. The highest rates of injury were for falls (60 per 1,000), recreational activities (57 per 1,000) and competitive sports (49 per 1,000). The site of care varied little by injury diagnosis or etiology, with the exception that sprains/strains, fractures, and injuries due to play and sports were more commonly treated in the clinic. The impact of trauma on activity was considerable, with 55.9 percent of injuries resulting in restricted activity, 10.6 percent in ≥2 days of school missed, and 6.7 percent in ≥2 days spent in bed. (*Am J Public Health* 1989; 79:990–994.)

Introduction

Injuries are the leading cause of death for children and young adults and a major cause of short- and long-term disability in the United States.[1] While advances in medical care have improved the outcome for some types of trauma, further significant decreases in morbidity and mortality will hinge on the development and implementation of effective prevention programs. As stated in the landmark report, *Injury in America*, "A prerequisite for the scientific study of injury is the acquisition of data on which to base priorities and research."[2]

Prior reports on non-fatal childhood injuries have focused almost exclusively on those injuries treated in the emergency room (ER) or hospital setting.[3–5] It is largely unknown, however, what proportion of all medically attended injuries are accounted for by injuries treated in the ER versus other sites; prior estimates place it at 40 percent for ER-treated injuries.[6] It is also not known in what way these injuries differ from those treated in a clinic or office setting, in terms of both etiology and type of injury.

Previous attempts to ascertain all medically attended injuries have significant limitations.[7–9] These include such problems as a recall bias and lack of important information on injury circumstances, etiology, treatment site, diagnosis, and severity.

The present study describes the incidence of unintentional injuries to children and adolescents 19 years of age and younger requiring medical care over a one-year period in a defined population, and compares the characteristics of injuries treated in the clinic to those treated in the emergency room setting.

Methods

A surveillance system was established to identify injuries treated in the clinic, ER, and hospital for children and adolescents 0–19 years of age who were members of the Northgate Medical Center of Group Health Cooperative (GHC) of Puget Sound. GHC is a large staff model health maintenance organization (HMO) serving approximately 330,000 members in the Puget Sound region.

Study Population

The group of children under surveillance during the study period October 11, 1985–October 10, 1986 were all enrolled as members of the Northgate GHC. This facility serves a population of 31,294 members, of whom 8,603 were 19 years of age or younger at the time of the study. As shown in Table 1, the study population is evenly distributed across age and sex groups. Nearly one-half of the study population heads-of-households had a college education, compared to 23 percent of the SMSA. The population also has a lower proportion of individuals in the lowest income category compared to the SMSA (14 percent vs 23 percent).

All GHC members are expected to and generally do receive medical care at their GHC clinic, emergency room, or hospital. In addition, audits of billing records for a 12-month period were done to identify patients with injuries treated outside the system and billed to GHC; these patients were included in the data presented. Finally, 7 percent of GHC enrollees have additional medical insurance. Injuries covered by this other insurance or paid out-of-pocket might be treated outside the GHC health care delivery system and would therefore be missed by the surveillance system established, resulting in a potential underestimate of injury rates.

Data Collection

Cases were identified through a daily examination of clinic and emergency room registration records by medical record technicians, using a specific protocol. Intentional injury cases, including child abuse, suicide attempts, and intentionally self-destructive actions were excluded. In addition, injuries due to complications of medical or surgical therapy, late effects of injuries, and illness due to food poisoning or contact dermatitis were also excluded. All other injuries falling within the International Classification of Diseases (ninth edition) codes 800–995 were included. An independent audit by study personnel of approximately 300 registration records found no injuries which had not been detected by this protocol. Age, sex, type of injury, and identifying data were abstracted from the record. Only the first visits for a new injury were included in the present analysis.

Injuries were sampled at 100 percent during the last eight months of the study; burns and admissions were sampled at

100 percent throughout the study period. The initial study (first four months) was undertaken as a thesis project by one of the authors (NC) and feasibility pilot with limited funding. Due to these circumstances, clinic and ER visits for injuries were randomly sampled at 25 percent and then 50 percent during the first four months of the study; sampling averaged 41 percent over this four-month period.

A detailed questionnaire about the circumstances of the injury and its consequences was mailed to the injured child's parent five to seven days after the initial visit to the emergency room or clinic. A reminder postcard was sent to all subjects not returning the questionnaire within one week. Non-responders were contacted by phone within four weeks of the medical visit and asked to complete the interview by phone. The overall response rate was 70.5 percent with 86.1 percent of the completed questionnaires done by mail and 31.9 percent by phone interview. Individuals responding by mail did not differ on the etiology of the injury, injury diagnosis, site of care, or household income from those in whom the questionnaire was completed by phone. These groups were therefore combined in the analysis.

Non-responders were compared to responders on age, sex, site of treatment, and type of injury. Non-responders did not differ from responders by sex distribution or site of treatment. The mean age of non-responders (11.70 years, SD = 5.36) was slightly greater than that of responders (10.50 years, SD = 5.30). Non-responders were also less likely to have more serious types of injuries such as fractures/dislocations (10.7 percent), lacerations (15.2 percent) and burns (2.7 percent) than responders (16.6 percent, 21.2 percent, and 4.2 percent, respectively).

Injuries were grouped into 14 different diagnostic categories according to ICD N codes, and into 12 different categories according to etiology or mechanism (Appendices A and B).

Rates of injuries were based on the 1,225 cases for which detailed questionnaire data were available. The total number of injuries in the study population was calculated by weighing for the sampling during the first portion of the study and for the non-response rate to the questionnaire in each sex and age category (<5 years, 5–9 years, 10–14 years, 15–19 years). Rates were calculated per 1,000 children using the number of registered members at the Northgate Medical Center in each age and sex group during the time period of the study.

Statistical testing was done using t-tests and Chi square as appropriate. Standard errors and confidence intervals were calculated based on the sampling and non-response rate.

Results

During the one-year study period, there was an estimated 2,127 injuries to the study population, for an overall incidence of 247 medically treated injuries per 1,000 children 0–19 years of age.

Age and Sex Variations in Rates and Sites of Treatment

As shown in Table 2, the majority of injuries, 1,266 or 59.5 percent, were treated in the clinic for an annual rate of 147 clinic-treated injuries per 1,000 children; the rate of ER-treated injuries was more than one-third lower at 100 per 1,000 (95 percent confidence interval of difference: 39.2, 54.8). There were 54 hospital admissions for an overall admission rate of 6/1,000 population or 2.5 percent of injuries. No child died from trauma in this population during the study period.

Consistent with previous studies, males had a higher rate of injuries than females, a difference which was greatest for the oldest age group. There were, however, no sex differences in the proportion treated in the clinic as compared to the ER. The rate of clinic-treated injuries was highest among 10–14 year olds, while 15–19 year olds had the highest rate of injuries treated in the ER. The proportion of injuries resulting

NOTE: The population for each sex age combination is as follows:
0–4 includes 1112 males and 1093 females
5–9 includes 1077 males and 1041 females
10–14 includes 1074 males and 1029 females
15–19 includes 1147 males and 1030 females
SE = Standard Error

in admission was similar for all age groups with the exception of the 10–14 year olds where the proportion admitted was lower at 1.6 percent.

Injury Diagnosis and Site of Treatment

The most common injuries were sprains/strains, lacerations/punctures, contusions/abrasions, and fractures (Table 3). The site where medical care was received varied little with the type of injury. As might be expected, strains/sprains were predominantly treated in the clinic, and lacerations more commonly in the ER. However, fractures were treated more than twice as frequently in the clinic than the ER. Injuries such as contusions and abrasions were seen equally in both sites. The highest proportion of injuries requiring admission were internal injuries (100 percent), head injuries (13.3 percent), foreign bodies (14.3 percent), and fractures (7.5 percent).

Etiology of Injury and Site of Treatment

Injuries were classified into 12 mutually exclusive etiologic categories (Table 4). The highest injury rates were for falls, recreational activities, and competitive sports; these injuries were more commonly treated in the clinic than the ER. Injuries due to motor vehicle collisions, burns, and those in the other/unknown category accounted for the highest proportion hospitalized.

Injury Impact

Time in bed, time lost from school, and limitations of activity were used to measure the impact of the injury (Table 5). Patients seen in the ER were more likely to stay two or more days in bed and, where applicable, miss two or more days of school than were children treated in the clinic. Overall, 55.9 percent of patients had some limitation in activity for two days or more due to the injury; patients treated in the clinic were somewhat more likely to have two or more days of limited activity than were patients treated in the ER.

Impact of the injury also varied with age and etiology. Older children were more likely to spend two or more days in bed, miss two or more days of school, and have more limitations of activity than were younger children. Motor

vehicle injuries resulted in the highest proportion of children spending two or more days in bed, while injuries due to sports had the highest rate of children missing school or resulting in limitations of activity.

Location of Injury Occurrence

The site of injury occurrence varied with the age of the child, as shown in Figure 1. Overall, 28 percent of the injuries occurred in the child's home or yard, with the highest proportion of injuries in the home in young children (60.3 percent). In contrast, the majority of injuries in the oldest age group occurred in school or the schoolyard (25.6 percent), the street (14.2 percent) or the athletic field (30.2 percent).

Discussion

The rates of injuries treated in the ER and clinic found in this study are comparable to rates found in some prior reports,[6,7] while substantially different from those reported in other studies.[3,4] In particular, the rate of ER treated injuries was substantially lower (100/1,000 0–19 year olds) than that reported by the SCIPP[4] (216/1,000 0–19 year olds) and NEOTS[3] (205–255/1,000 0–14 year olds) studies. By contrast, the rate of medically treated injuries, 257 per 1,000 individuals 0–20 years of age, available from a special injury supplement to the 1975 National Health Interview Survey (NHIS)[6] is very similar to ours. One other study of an HMO population, performed 25 years ago by Manheimer, *et al*,[7] at a Kaiser Permanente clinic in Oakland, reported a rate of medically treated injuries identical to ours—246 per 1,000 0–15 year olds. The rate of hospitalized injuries in our study (6/1,000) was similar to the rate reported by the SCIPP study in their ER surveillance (7.7/1,000).

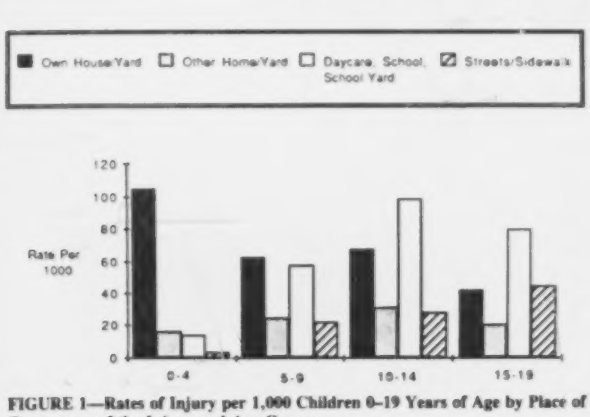

FIGURE 1—Rates of Injury per 1,000 Children 0–19 Years of Age by Place of Occurrence of the Injury and Age Group

These differences in rates may be a reflection of different socioeconomic groups in these studies, the form of medical care coverage available, or differences in care seeking behavior. Data from a number of studies clearly indicate that poor children have a higher rate of fatal injury than non-poor children, and probably a higher rate of certain types of non-fatal injuries as well.[10–12] Our study population was somewhat better educated and were less likely to be in the lowest income group than the surrounding SMSA; these differences may thus be partly responsible for the lower rate of ER-treated injuries reported.

Health care seeking patterns of members of HMOs might be different from the general population as well. At GHC, greater than 80 percent of members are specifically identified with a particular primary care physician. Under these circumstances it is reasonable to suppose that members will seek care at the lowest level (primary care) which can manage the problem, since this represents the specifically identified and most accessible care to the members. Thus, one might anticipate a shift of visits for injuries from the ER to the clinic. Although this likely occurred to some extent in our study population, the proportion of patients treated in the ER at GHC is similar to national data from the NHIS.[6] In that study, 46.7 percent of the medically treated injuries were seen in the ER compared to 40.2 percent in this study.

Our study has certain limitations which must be recognized. The incidence of injuries reported is probably an underestimate of the true rate because of non-GHC care covered by additional insurance or out-of-pocket expenditures by GHC members. As discussed earlier, 7 percent of members have the former; the extent of the latter is unknown.

The data are based on a sample (N = 1,225) out of a total of 2,127 injuries estimated to have occurred in the one-year period of surveillance. This is a reflection of the initial random sampling rates of 25 percent and later 50 percent in the first four months of the study. This procedure should not have introduced significant bias since the number of injuries were relatively large by type and etiological category, resulting in small standard errors and reasonable confidence intervals for most rates. In addition, the sampling did not appear to introduce a seasonality bias, since the proportion of injuries in each etiological category was similar during the first four months as compared to the subsequent eight months.

The data are based on a sample of patients, reflective of both the initial sampling scheme and the 70.5 percent response rate to the questionnaire. However, since the number of injuries was large the standard errors in most analyses were small, giving relatively narrow confidence intervals. Because of differences between non-responders and responders, the data underestimate injuries to younger children and less serious types of injuries such as contusions and abrasions.

The present study indicates that a large proportion of childhood injuries requiring medical care are treated in the clinic rather than in the ER setting. In our study, there were striking similarities in both etiology and diagnosis between those injuries treated in the clinic and those treated in the

emergency room. In addition, the study indicates that those injuries treated in the clinic result in a higher rate of limitations in activity. Thus, surveillance systems which collect data only on ER-treated injuries will miss injuries which are important (in terms of both frequency and impact) to the child and family. Injuries treated in both settings are important targets for prevention programs.

ACKNOWLEDGMENTS

We wish to thank Polly Allen and the other Northgate Medical Center registrars for their help in identifying patients, Rick Chandler for conducting the interviews, Amarjit Sandhu for data analysis, and Lincoln Pollisar for biostatistical consultation.

Definition of Injury Etiology

	Injury Type	Definition
E 880–819	Falls	Excludes falls from motor vehicles, during competitive sport activities, and during recreational activities such as bicycling, skiing, jogging.
—	Play/Recreational	Includes bicycling, skating, jogging, skiing, everyday play.
—	Sports	Traditional competitive sports including baseball, basketball, football, soccer, hockey, etc.
E 810–819	Motor Vehicle	All injuries involving motor vehicles, including pedestrian- and bicycle-motor vehicle collisions.
E 820–825		
E 890–899	Burns	All burns including flame and scald.
E 924, 926		
E 850–869	Poisoning	Inhalation or ingestion of toxic substance, drugs other solid, liquid or gas.
E 910	Drowning	Submersion.
E 911–913	Choking, Aspiration, Suffocation, Asphyxiation	Mechanical suffocation, asphyxiation by food or other object.
E 916	Struck by Falling Object	—
E 919–920	Cutting Object	Injury by cutting or piercing object including machinery.
E 921	Struck by Other Person	Excludes child abuse.
—	Other	All other injuries.

A Case-Control Study of Pedestrian and Bicyclist Injuries in Childhood

I. Barry Pless, MD, Rene Verreault, PhD, and Sonia Tenina, MSc

Abstract: We identified children ages 0 to 14 years injured in traffic as pedestrians or bicyclists in Montreal, Canada. Two hundred children with injuries who received a score of 2 or more on the Maximum Abbreviated Injury Severity scale were considered as cases and compared with 400 uninjured children seen in the same hospitals for non-traumatic reasons. Systematic, blinded interviews and tests were conducted with parents to determine the role of a series of social, familial, personal, and behavioral characteristics. After adjustment for age, gender and socioeconomic area of residence, logistic regression analyses showed higher risks of injury to be related to fewer years of parents' education, a history of accident to a family member, an environment judged as unsafe, and poor parental supervision. Absence of physical health problems, fewer family preventive behaviors and reported lack of cautiousness were also related to a higher risk, whereas neither aggressivity nor behavioral disturbance, whether internalizing or externalizing, showed any such relation. These data suggest that the child's personality and behavior are weaker risk factors for pedestrian and bicyclist injuries than are family and neighborhood characteristics. (*Am J Public Health* 1989; 79:995–998.)

Introduction

Traffic accidents are the principal cause of mortality and morbidity among children.[1,2] Although in recent years much effort has been invested in descriptive studies of seat restraint use among child passengers,[3] and in evaluating programs designed to enhance use, much less is known about factors that place child pedestrians and bicyclists at risk for injuries in traffic. As a consequence, there are few well established strategies for the prevention of these injuries. Many of the most popular of these strategies rely on health education approaches, the efficacy of which appears to be distinctly limited.[4] Strong evidence has been presented to demonstrate that boys are more frequently injured in traffic than girls, and that living in lower socioeconomic areas is a risk factor.[5] However, assertions that behavioral factors[6,7] contribute to "accident-proneness"[8,9] or that family factors increase the risk of injury[10] are still open to question.

The present study describes the strength of a series of hypothesized risk factors for child pedestrian and bicyclist injuries using a case-control research design. Since many of these events result in injuries of minor severity and hence of little public health significance, the analyses reported here are restricted to cases of greater seriousness, as defined below.

Methods

All children (N = 1,600) under age 15 years injured in a traffic accident from July 1980 to December 1981 were identified through regular monitoring of 10 hospitals in the metropolitan area of Montreal and after a complete review of police accident reports.[11] This group includes virtually all children resident on the Island of Montreal who were treated in an emergency room (ER) for an injury from a passenger, pedestrian, or bicyclist accident during the 18-month study period. Their characteristics have been described in a previous report.[12]

Cases in the present study were 200 children who were seen in the city's two children's hospitals with pedestrian or bicyclist injuries that received a score of 2 or more on the Maximum Abbreviated Injury Scale (MAIS).[13] The score increases with severity of injury from 1 to a maximum of 6, for death. An MAIS score of 2, which was chosen as the minimum severity for inclusion, corresponds to fractures, dislocations, or deep lacerations. The cases included 130 hospital admissions. Thirteen children who died from traffic injuries during the study period are not included.

Two groups of non-injured controls were selected from patients treated for medical problems in the same ER as the cases. The first, group 1, included 200 children matched by hospital, age (±2 years), sex and socioeconomic area (SEA) of residence (ranked high, low, and middle from census tract variables, e.g., father's occupation, family size and housing conditions).[14] The second, group 2, intended as a random sample, included 200 children but was only individually matched on hospital and frequency matched on age in the following categories: under age 5, 5–9, and 10–14 years. Medical problems that prompted ER visits by controls included, for the most part, colds, ear infections, and other minor complaints.

After each subject was identified, an interview with the mother was scheduled either at home or in the hospital depending on the condition of the child. The interview took place two to four weeks following the ER visit. Interviewers were intended to be unaware of the status of the subject, although in some cases this was not possible. The interview included the Child Behavior Checklist[15] and a structured questionnaire about sociodemographic and family characteristics, safety of the child's environment, extent of parent supervision, and the child's behavior and temperament characteristics.

All items in the questionnaire were summarized into a series of distinct hypothesized risk factors. Some factors were created as indices using several items that were first dichotomized and assigned a value of 0 or 1 according to the postulated direction of risk based on current knowledge. Indices were then calculated by summing this value and categorized into three or four groups. For example, a "family stress" index was created from the reported occurrence of 19 specific stressful events in the family during the six months preceding the ER visit (e.g., death of a family member, divorce, problems at work or at school, financial problems). A "preventive behavior" index (five items) related to the child's behavior when crossing streets, the use of automobile seat

restraints, and the parents' attitudes toward safety. An "environmental risk" index was created from four items describing the parent's assessment of traffic density and general safety of the immediate neighborhood. Finally, a "parental supervision" index (seven items) concerned safety related restrictions and cautions given to the child. In the latter, children under age 6 years were arbitrarily classified as being "at risk" with respect to the following: awareness of dangers when crossing between parked cars, understanding road safety rules, and having received formal safety instruction.

The scores on the Child Behavior Checklist serve to supplement a set of bi-polar personality descriptors included in the interview. Abnormal scores on this measure, which has been standardized and has established norms,[15] identify disturbed children similar to those receiving mental health services. Those with abnormal scores can be further categorized into those with disorders that are primarily "internalizing" (neurotic, withdrawn) and those that are "externalizing" (antisocial, aggressive). The results of the Child Behavior Checklist, completed by the parent, are expressed as normalized T scores, with scores greater than 63 representing those above the 90th percentile and hence abnormal.

Associations between the hypothesized determinants and the risk of pedestrian or bicyclist injury are presented as relative risks (RR). All analyses were performed using unmatched procedures after combining the two control groups.[16] This decision was reached after examining the results from preliminary analyses with each control group separately, using both matched and unmatched techniques, and finding little difference. All estimates of RR were obtained by unconditional logistic regression.[17] Logistic models included age (under 5, 5–9, 10–14 years), sex and SEA (low, middle and high) as confounding variables, because these were used as matching factors. For each analysis, the model included a single exposure variable, being assigned a reference value within each category, and all confounding variables. The ratio of the coefficient of the exposure variable to its standard error is presented with its corresponding p value and allows testing of the hypothesis that ln(RR) increases linearly across categories as a test for trends.

Results

Table 1 gives the distribution of age, gender, and SEA for cases and both groups of controls. Group 1 is similar to cases by age and gender but not quite as closely matched by socioeconomic area as intended. Group 2 also differs with respect to the sex ratio and thus reveals the expected increased risk of pedestrian and bicyclist injuries among boys. The number of cases peak in the 5–9 year age group.

Relative risks (RR) and 95% confidence intervals (CI) are presented in Table 2 for social and family determinants of injury after adjustment for age, sex, and socioeconomic area of residence. A high level of parents' education was strongly related to a lower risk of injury. Previous accidents of any family member requiring hospitalization as well as a low level of parental supervision and a high index of environmental risk were also associated with an increased risk of injury. Larger family size was related to increased risk, but this trend was less pronounced. Mother's employment and family stress were weakly and inversely related to risk.

Table 3 relates the hypothesized personal and behavioral determinants to risk of injuries. The presence of a physical problem—such as a chronic disability or impaired vision or hearing—was related to a reduced risk. Conversely, children with a low index of preventive behavior or a low level of cautiousness were at significantly higher risk. Nonsociability was associated with a slight increase in risk, whereas level of aggressivity showed no relation.

The presence of a behavioral problem, as assessed by the Child Behavior Checklist score, was also not related to the risk of injury (Table 3). Neither an internalizing nor externalizing behavior pattern was associated with the risk of traffic injuries.

All variables were again assessed in individual logistic regression analyses. Additional adjustment of the effect of each risk factor for all other established factors in a single regression model was performed but had little effect on the estimates of RR and therefore is not presented.* Finally, the relations of social, familial, personal, and behavioral factors to the risk of injury were examined within levels of age, gender and socioeconomic area. A previous accident was related to higher risk mainly among children being in low socioeconomic areas and the relation of a high family stress index and low risk was only observed among children in high socioeconomic areas. No other differences of consequence were observed over each level of age, gender and socioeconomic area.*

Discussion

These findings are in sharp contrast to those of some investigators who report maladjustment or disturbed behavior [6,7,18,19] but consistent with others.[20,21] Although there is a large literature on behavioral abnormalities of children who have been injured, and those who are "accident prone," few of the former studies report consistent behavioral abnormalities. In contrast, two reports suggest that activity level and/or aggression are significantly associated with the occurrence of subsequent injuries.[20,21] Such findings are difficult to compare, because the nature of the injuries are often different, as are the measures of behavior. However, to the extent that over-activity may be equivalent to lack of cautiousness, our findings agree with those of the latter investigators using longitudinal data.

It is also often difficult to interpret what behavioral relationships with injuries mean. For example, one study[7] suggests that behavioral characteristics may predict injuries differently among "normal" healthy children who are simply being adventuresome, extroverted and curious, compared to those with clinical behavioral disturbances leading to withdrawal and who may have a diminished ability to cope with environmental demands and the tasks needed to ensure safety. Our findings suggest that behavioral disturbance as such plays little role in the prediction of injuries, whereas traits such as lack of cautiousness may be of some importance.

It is not surprising that having a physical health problem appears to reduce risk of injury, but the wording of the question does not enable us to determine whether the association exists because these children are less exposed, more cautious, or more closely supervised.

Of greatest interest are the remaining risk factors. The first of these relates to the nearly three-fold increase in risk among children in the lowest category of the preventive behavior index. Although this may partly reflect post hoc reporting problems, it appears that children in families where parents admit engaging in many unsafe preventive behaviors—such as not using seat restraints in motor vehicles—truly have an increased likelihood of having a traffic injury.

The credibility of this interpretation is supported by the finding that when any member of the family has been seriously injured previously, the risk to the child is increased by about 50 percent. (This is not confounded with family size since the finding remains after adjustment for all other risk factors.) Parental supervision was also self-reported and hence subject to possible distortion, but not to social desirability bias. This strong association is consistent with a pattern of risk as a family issue rather than a personal one. This too is in keeping with other reports.[23,24]

Also compelling are the strong relations with reported safety of the environment where most of the children were injured. Here again, the question of reporting bias must be acknowledged. Parents whose children have been injured may understandably exaggerate the degree to which their neighborhood is dangerous. Against this, a number of other

reports show strong associations between injury rates and areas characterized by few parks, few bicycle paths, poorly designed intersections, and dense traffic.[25,26] And, perhaps most importantly, these may also be areas where driving behavior is most dangerous.[27,28]

In summary, although these results provide some evidence that the behavior of the child or parent plays a role in increasing the risk of traffic injuries among children, they provide a much more compelling argument for examining more closely the risks associated with environmental factors. In communities where urban planning has taken the safety of the child into account, specifically through measures aimed at separating traffic from bicyclists and pedestrians, there appear to be significantly fewer injuries.[29,30] Although few of these reports provide conclusive evidence of the effectiveness of these preventive strategies, it seems promising that those responsible for developing injury prevention strategies for a community to take full account of such features of the environment. The alternative is to continue to "blame the victim," in this case the child, by focusing on imprudent behavior, or to further emphasize the parent's obligation to provide better supervision. Either of these strategies, while not entirely misplaced, are much less likely to result in a significant reduction in traffic-related injuries in the short run than would programs aimed at changing the behavior of the driver or improving urban environments through traffic engineering.

4th National Conference on Chronic Disease Prevention, Control

The Centers for Disease Control (CDC) and the Association of State and Territorial Health Officials (ASTHO) will cosponsor the Fourth National Conference on Chronic Disease Prevention and Control: "Implementing Effective Strategies," September 20–22, 1989, at the Bahia Hotel in San Diego, California. The conference is open to the public; there will be no registration fee.

The conference will emphasize the interactions among federal, state, and local health departments, voluntary health agencies, professional organizations and others, and will include plenary sessions that address legislation, surveillance, and year 2000 health objectives. Concurrent sessions will focus on: screening and quality assurance; evaluation, diabetes and obesity; childhood antecedents of chronic disease; emerging issues, programs, and controversies in chronic disease prevention and control; barriers to risk-factor modification among minorities; and nutrition and cancer. For additional information, contact Jack Friel, Center for Chronic Disease Prevention and Health Promotion, Mailstop A37, CDC, Atlanta, GA 30333; tel: (404) 639-2249 or FTS 236-2249.

Comprehensive Health Care for High-Risk Adolescents: An Evaluation Study

FELTON EARLS, MD, LEE N. ROBINS, PHD, ARLENE R. STIFFMAN, PHD, AND JACK POWELL, PHD

Abstract: This study was designed to evaluate the effectiveness of a large scale program to improve health care for high-risk adolescents. Seven clinics, funded to provide comprehensive primary care to adolescents, were compared to three non-funded clinics. The majority of the 2,788 adolescent patients sampled in these clinics were female (78 percent) and Black (71 percent). Each patient was initially interviewed at the time of a clinic visit and reinterviewed 12 months later; their medical records were systematically reviewed. As expected, the funded clinics detected and treated a wider range of medical and behavioral problems than the comparison clinics, a finding that was based on the self-reports of patients and confirmed by documentation in the medical records. However, improvements in life-style and in specific medical outcomes were not observed. To build on the limited success of this program, efforts are needed to encourage more males to receive care and to develop more specific interventions for patients in this age group. (*Am J Public Health* 1989; 79:999–1005).

Introduction

The problems adolescents take to doctors challenge conventional approaches to medical care. To promote a focused and intensive effort to improve the health care of young people, adolescent medicine[1–4] has been quick to identify the major causes of mortality and the most common morbidities characterizing this age group[5]; less certainty exists on knowing how effective interventions have been in improving the health of adolescents, however.[1–5] To a large extent this is because the approach to problems such as unprotected sexual intercourse, substance abuse, and violent behavior require behavioral and life-style changes that go beyond traditional medical practices.

Results of a broad-scale program to improve the health care of high-risk populations of adolescents are reported in this paper. The project, introduced as the Program to Consolidate Health Services for High-Risk Young People and sponsored by the Robert Wood Johnson Foundation, was started in 1981. Twenty medical schools were selected to receive funds to provide comprehensive services to youths at higher risk than the national average for the major problems characteristic of this age group, and by improving the training of physicians in adolescent medicine.[6]

The concept was based more on the capacity to provide comprehensive health services than on the organizational characteristics of the participating programs. For this reason the evaluation was guided by five objectives:

1) Do the funded clinics attract truly high-risk youths?
2) Do they detect their problems?
3) Are comprehensive services provided?
4) Are these services implemented?
5) Are health outcomes improved?

To address these questions, the clinics receiving grants from the Johnson Foundation were compared to a group of clinics that did not have a special focus on adolescents. Because of their location in inner-city areas, all of the clinics were in a position to serve high-risk youths.

Methods

Research Design

The research design was that of a two-wave survey in which youths attending primary health clinics were interviewed twice at a 12-month interval. Of the 20 funded clinics, seven were chosen to participate in this evaluation study because they had a relatively large volume of patients in the adolescent age range from which to sample. The 20 clinics linked medical school training programs in adolescent medicine to a range of services based in hospitals, neighborhoods, and schools. However, each program was given considerable leverage in choosing how to develop a consolidated program. Of the seven programs studied, five had clinics in multiple settings including three with school-based clinics; those that operated from a single locus had established ties with other services; all seven had multidisciplinary staffs that included social workers, psychologists, special education counselors, midwives, and recreational counselors as well as physicians and nurses.

The seven funded programs (all associated with academic medical centers in Boston, MA; New Haven, CT; Indianapolis, IN; Chicago, IL; Jackson, MS; Dallas, TX; and Los Angeles, CA) were compared to clinics that were part of three non-specialized services (located in Buffalo, NY; St. Louis, MO; and New Orleans, LA). The comparison clinics did not offer special services to teenagers, nor did they have training programs in adolescent medicine. They were typically staffed only with physicians and nurses and had few administrative ties to other community-based clinics; none operated school-based clinics. The funded and non-funded clinics were similar in that they were all located in major public medical centers in their respective cities and were accessible to indigent patients. A brief description of the 10 programs, highlighting some of their similarities and differences, is provided in Appendix A.

Sampling

Between 150 and 360 youths were sampled from each clinic between November 1984 and May 1985. The age range of patients was restricted to 13–18 year olds. The sample represented a series of consecutive and unduplicated teenage patients appearing on days when the clinics were operating. The variation in the number sampled reflected the volume of patients in this age range attending the clinics during this six-month period, and in that sense the patients are representative of a typical day in the operation of primary health

clinics. Most were interviewed on the same day that they attended the clinics in an on-site space where confidentiality could be maintained and their medical care not compromised.

During the six-month field period of Wave 1, 3,102 patients became eligible to participate in the study, based on their age and presentation at one of the clinics. Of these, 2,788 were interviewed. Among the 314 patients who were identified but not interviewed, 115 refused; 199 were not interviewed either because they were over the age of 18, too ill, or could not be located during or following their visit. Eighty-seven percent of those interviewed during Wave 1 were reinterviewed 12 months later during Wave 2. Because of the time consumed in locating and reviewing medical records, only about 83 percent of youths completing both the Wave 1 and Wave 2 interviews had their records abstracted. Complete data are available for 72 percent of the original sample.

There were no substantial differences in the number of patients completing all aspects of the study in the three types of programs, as shown in Table 1.

Interviews and Record Reviews

Highly structured interview protocols covered the youths' reasons for attending the clinics, other health services used, their physical and mental health status, family background, school adjustment, peer relations, stressful events, social adjustment, social supports, health practices, and extracurricular activities. Sections of the interview dealing with depression, anxiety, alcohol/drug use and abuse, tobacco use, and physical symptoms were taken from the Diagnostic Interview Schedule (DIS).[7] A section on aggressive and antisocial behavior was taken from the Diagnostic Interview for Children and Adolescents (DICA).[8] The follow-up interview, completed 12 months after the initial interview, covered these same issues and assessed change in health status and satisfaction with services received. During this second wave, the medical records of the youths were reviewed and abstracted.

At the Wave 2 interview, (75 percent of which was done at home) particular treatment for problems that had been identified in the Wave 1 interview was also queried. These problems included the presenting problem for which the youth was seeking help as well as any others reported during the interview session, regardless of whether or not they were known to health personnel at the study clinic.

TABLE 1—Sample Sizes at Wave 1 and Wave 2

		Of Those Completing Wave 1			
	Total Number Interviewed at Wave 1	Completed Wave 2 Interview		Completed Wave 2 Interview and Had Medical Record Review	
Type of Clinic	N*	f	%	f	%
Funded NH	1320	1087	(82)	925	(70)
Funded S	616	568	(92)	452	(73)
Comparison	852	760	(89)	625	(73)
Total	2788	2415	(87)	2002	(72)

*This number represents 86%, 97%, 92%, and 90% of all eligible cases in the Funded NH, Funded S, and Comparison clinics and the total sample, respectively.
NH - Neighborhood/hospital-based
S - School-based

A structured protocol, designed to complement the interview, was used to abstract information from the medical records. The interviewing and record reviews were done by professional interviewers (Survey Research Associates of Baltimore) who were trained prior to each wave of interviews. An effort was made to collect records from all services used by patients even if they were not affiliated with the study programs.

Results

Sample Description

Females made up over three-fourths of the sample and Blacks represented 71 percent. Black females constituted the largest sex-race group and were the most uniformly distributed across all the sites, while White males represented the smallest and least well distributed group. Of the three types of clinics, the school-based clinics had the largest proportion of males (43 percent), followed by the funded neighborhood/hospital-based clinics (21 percent), and the comparison neighborhood/hospital-based clinics (12 percent).

This patient sample is unrepresentative of the general population of youths who lived in the urban areas where the clinics were located. In some cases, youths originally residing outside these areas were attracted to these clinics because they wished to avoid stigma or sanctions that might have accompanied help-seeking in their own communities. Even among those living in the same areas as the clinics, self-selection operated to yield a group in which females predominated and males not in school were underrepresented. In the neighborhood and hospital-based clinics, 19 percent of the youths were not in school, a rate which varied from 4 percent for Black males to 42 percent for White females. Fifty-seven percent of the youths' families were headed by persons with blue collar jobs, and 7 percent of their breadwinners were unemployed. Nine percent of the youths lived in circumstances in which there was no parent or parent surrogate present.

Presenting Problems and Risk Factors

Table 2 shows the frequency of the presenting problems reported at the initial interview. Over three-fourths of the youths were attending for problems unrelated to illness (i.e., pregnancy, birth control, check-up, and preventive care), a percentage that varied from 61 percent in the funded neighborhood/hospital-based clinics to over 90 percent in the comparison clinics. Those attending the funded clinics had higher rates of utilization for acute medical problems, contraceptive needs, mental health problems, sexually transmitted diseases, and chronic illnesses than those in the comparison clinics; and lower rates for pregnancy. Not unexpectedly, the school-based clinics attracted the largest proportions of youths requesting check-ups and other forms of preventive care. These differences among the three types of clinics remained after controlling for age, race, and sex.

Table 3 shows the percentage of individuals attending the three types of clinics who had ever experienced a variety of life-style and behavioral problems. A cumulative index was derived by summing the presence of each problem over the life-span prior to Wave 1 and its occurrence (or recurrence) in the interval between Wave 1 and Wave 2 interviews. The definition of each risk factor is given in Appendix B. As a measure of highest risk, the proportion of youths with three or more of these risk factors is included in Table 3. These indicators represent some of the major risks for injury and social problems in adolescents and, quite apart from their

TABLE 2—Percentage Distribution of Presenting Problems of Adolescents at Three Types of Clinics

3+ Problems	60	41	64	57

presenting problems, should be of keen concern to health providers.

The school-based clinics had the lowest proportion of high-risk youths (41 percent) and these youths had lower rates on all but one (fighting) of the 11 individual risk factors compared to youths in the other types of clinics. Engaging in physical fights and unprotected sexual activity (shown by the proportion with contraceptive needs) were the most common problems. Suicidal behavior was the least common.

Pattern of Utilization and Care

To examine the impact of the funded programs, 11 problems were selected that included both traditional medical conditions, such as asthma and sexually transmitted diseases (STD), and behavioral and life-style problems, such as those listed in Table 3. The list, based on problems designated by the youths in the initial interviews regardless of whether or not such problems constituted the reason for seeking care, conforms to the types of problems targeted by the funding agency in its charge to improve services for high-risk youths.

Table 4 illustrates the extent to which this range of health problems was recognized and treated in the three types of clinics. The most important contrast is between the funded neighborhood/hospital-based and the comparison clinics, since they were located in similar settings. The funded school-based clinics provide data to contrast with the neighborhood/hospital-based clinics. The Table shows that youths in the funded clinics were more likely to inform providers about their behavioral and life-style problems than youths in the comparisons clinics. On the other hand, informing the clinics about more clear-cut medical problems (contraceptive needs, asthma, injury and STD) was done with greater consistency and at higher rates among all clinics than they were for behavioral and life-style problems.

Informing a clinic about a problem constitutes a first step toward getting help. Table 5 shows the proportion of youths who actually received help among those who had told a clinic about their problems. In most cases, help was obtained on-site. But because having the capacity to refer patients to other services when needed was a key element of the effort to consolidate services, it is also included in the Table. Youths with asthma and conduct or interpersonal problems in the funded clinics were more likely to be treated on-site than youths in the comparison clinics. What is most striking, however, is that the numbers of youths available to be treated in the comparison clinics were greatly reduced because fewer had informed the health care providers about their life-style and behavioral problems. Differences in the rate of referral among the clinics were not striking.

Medical Record Documentation

While the research interview was designed to comprehensively assess the health and psychosocial status of the youths, providers were faced with the need to specifically address the patient's presenting problem. Within the limited and often pressured time frame of most patient encounters, they also had to conduct a general examination of their patients and record their findings in the medical record.

We compared the youths' health and psychosocial profiles based on data from the interview to that abstracted from the medical records by counting the number of problems identified in each document using a common list such as that

TABLE 4—Percentages of Youths Who Returned to the Clinic between Waves 1 and 2 and Informed Providers about Their Health Problems in Funded Neighborhood/Hospital Clinics (N = 1087), Funded School Clinics (N = 568), and Comparison Clinics (N = 760)

FNH - Funded neighborhood/hospital-based clinics
FS - Funded school-based clinics
COM - Comparison clinics

shown in Table 4. The findings are shown in Figure 1. As expected, the interviews provided more information than the medical records. The largest discrepancy occurred in the comparison clinics. While youths in the funded neighborhood/hospital-based clinics and the comparison clinics had the same mean number of risk factors based on the interview data, the number of risk factors documented in the records was significantly higher in the funded clinics. This supports the self-reports of the youths and indicates that funded clinics were clearly superior to the comparison clinics in detecting a broad range of health problems in their patients.

Outcome Measures

Two approaches were taken to detect differences in outcomes between youths in the funded and comparison clinics. One approach was aimed at detecting changes in the number of behavioral and life-style problems in the 12-month period preceding the Wave 1 and Wave 2 interviews, and the other examined the degree of recurrence or persistence of specific medical or psychiatric problems. No evidence was found favoring the funded clinics in either case. The proportion of youths experiencing three or more risk factors in the year preceding the Wave 2 interview remained the same as it had been in the 12 months preceding the Wave 1 interview in both the funded and the comparison clinics. Even when age, race, sex, and the number of problems present at Wave 1 were controlled, the risk status of the youths at Wave 2 was not diminished in the funded programs. This was true not only when the proportion of youths with multiple problems was examined, but also for a reduction in the average number of behavioral and life-style problems reported in the year following the initial interview. In fact, there was a small increase in the proportion of youths with multiple problems suggesting that the interventions were not able to overcome the expectable increase in risk associated with the aging of an adolescent sample.

A number of specific outcomes were examined next. The frequency of sexually transmitted diseases in the interval between Waves 1 and 2 among youths with a previous history of such infections was not reduced in the funded clinics compared to the nonfunded clinics. This was also true for having a second (or third) pregnancy. In fact, for most of the problems examined, we failed to find evidence of a reduction in risk among youths attending the funded clinics. Although the proportion with unmet contraceptive needs remained uniformly high in all the clinics, we found, unexpectedly, that the proportion with persisting depressive symptoms and heavy alcohol/drug use at Wave 2 was actually higher in youths in the funded neighborhood/hospital clinics than in the comparison programs, as shown in Table 6.

Discussion

The answer to the first question of this evaluation study—"Do the funded clinics attract truly high-risk youths?"—is affirmative. Nearly two-thirds of the youths attending the neighborhood and hospital-based clinics had multiple behavioral and life-style problems that placed them at high risk for the social morbidities characteristic of adolescence and young adulthood and for early death. However, the proportion of such youths in the funded clinics was no greater than that in the comparison clinics. All the clinics turned out to be particularly appropriate places to reach high-risk females, a finding supported by another recently completed study of an adolescent clinic in a suburban setting.[9] While the school-based clinics had a lower proportion of high-risk youths, they attracted more males than did the neighborhood/hospital-based clinics. All of the clinics, however, failed to attract males who were not in school. This remains a challenge since these males represent the highest risk group for intentional and unintentional injury in the community. One approach to attracting a larger number of high-risk males is through liaison with juvenile detention facilities. This was pursued by one funded neighborhood/hospital-based clinic which, not surprisingly, had the highest proportion of males attending these types of clinics.

Clinicians in adolescent medicine are faced with detecting and treating a spectrum of problems for which traditional pediatric training may not have thoroughly prepared them. In addition to traditional medical problems, such as sexually transmitted diseases, and pregnancy, their experience must also alert them to the importance of behavioral and life-style problems such as depression, delinquency, substance abuse, unprotected sexual intercourse, and cigarette smoking.[10] For this reason we were especially interested in the answer to the second question of the evaluation regarding the detection of a broad range of health and social problems in adolescent patients. The superiority of the funded clinics in recognizing

behavioral and lifestyle problems was clearly shown by the higher proportion of youths reporting such problems to them and by their more extensive demonstration of such problems in their medical records.

No doubt the greater recognition of problems in the funded clinics was a function of their more diverse and specially trained staffs. Their success in this regard resulted in more youths receiving treatment and interventions being provided for a broader range of problems than in the comparison clinics. This answers the third question of the evaluation regarding the availability and implementation of comprehensive services.

It is worth emphasizing that, although the quality of care was not directly assessed, a higher quality of care in the funded clinics can be inferred from their more extensive documentation of problems.[11,12] Nevertheless, the funded

TABLE 6—Percentages of Youths with Persistent Problems from Wave 1 to Wave 2* in the Three Types of Clinics

Type of Clinic	Persistent Depressive Symptoms %	Unmet Contraceptive Needs %	Heavy Alcohol or Drug Use %
FNH (N = 1087)	23[a]	36	31[b]
FS (N = 568)	12	29	18
COM (N = 760)	14	33	21

*Persistence is defined as the presence of the problems in the 12 months prior to the Wave 1 interview and again in the 12-month interval between the Wave 1 and Wave 2 interview.
a) FNH - COM = 9% (95% CI = 5.5, 12.5)
b) FNH - COM = 10% (95% CI = 6.0, 14.0)

clinics were not able to alter the propensity of their patients to continue their adverse life-styles and to accumulate additional problems.

There are at least three reasons to explain why we failed to detect outcome differences:

- The follow-up period of one-year was a short interval over which to find differences in problems many of which have their bases in lifestyle orientations.
- More time may be needed to judge the impact of specialized primary health care for adolescents since pediatricians have only recently begun to develop skills in these areas. One goal of the Robert Wood Johnson Foundation was to inspire efforts to develop training programs and to promote the concept of interdisciplinary, consolidated health care for this age group. While the Foundation's initiative was clearly successful in supporting many new programs throughout the country, the long-term success of this field will depend on the extent to which stable support is found to maintain its focused agenda.
- A more sobering reason why we may not have detected outcome differences relates to the inherent nature of many of the problems characteristics of high-risk youths. Perhaps their difficulties are so deeply embedded in the economic and social contexts from which they come that improvements in their health status require more than medical clinics can provide. If this is the case, then the goals of treatment should relate more to the stabilization of risk conditions, than to their actual reduction.[13]

There are two limitations of the present study that deserve special mention. As in many evaluation studies, the research design for this one was developed after the programs had already been funded. This resulted in less comparability among the clinics in their organizational patterns and in the character and intensity of the interventions they provided. The other limitation relates to the possibility that biased reporting of health-related information occurred in the interviews. Efforts were made to minimize this problem by using highly structured and carefully validated interview methods, systematic training, and monitoring of interviewers, and by comparing information derived from the interviews with that included in medical records.

Overall, the evaluation demonstrates that the Johnson Foundation's objectives met with limited success. Continued progress in the identification of the behavioral and life-style problems possessed by these youths must be followed by finding ways to attract more males as patients and by devising interventions that, at a minimum, have the capacity to slow down the progression of life-style and behavioral problems that are typically occurring at their peak rates during the later adolescent years.

APPENDIX A

Ten Participating Clinics Included Seven with Adolescent Services (Funded Clinics) and Three with Non-specialized Services (Comparison Clinics)

Funded Clinics

1. A hospital-based adolescent clinic, a neighborhood-based adolescent clinic, and a school-based clinic were included in this program in New Haven, Connecticut. The multidisciplinary staff included an adolescent medicine specialist, fellows in adolescent medicine, a nurse-midwife, a social worker, and a psychologist.

2. A hospital-based adolescent clinic, a neighborhood-based clinic, and a school-based clinic were components of the program in Chicago, Illinois. The staff consisted of an adolescent medicine specialist, fellows in adolescent medicine, a nurse practitioner, a school nurse, a social worker, a guidance counselor, and a special education counselor.

3. Two high-school-based clinics, with neighborhood and hospital-based clinics serving as part of a consolidated network, composed the program in Jackson, Mississippi. The staff included an adolescent medicine specialist, fellows in adolescent medicine, a nurse, a social worker, and an educational counselor.

4. A hospital-based clinic and a neighborhood-based adolescent clinic made up this program in Boston, Massachusetts. The staff was composed of adolescent medicine specialists, fellows in adolescent medicine, a nurse, a psychologist, and a recreational counselor; the program also sponsors a school-based violence prevention program.

5. This program in Dallas, Texas consisted of a hospital-based adolescent clinic that placed emphasis on screening and diagnostic evaluation. It tied to an extensive referral network of neighborhood-based clinics throughout the city. The multidisciplinary staff included an adolescent medicine specialist, fellows in adolescent medicine, a nurse, a nurse practitioner, a social worker, and a consulting psychiatrist.

6. A neighborhood-based adolescent clinic and a closely associated hospital-based adolescent clinic constituted the two components of this program in Los Angeles, California. The staff consisted of a specialist in adolescent medicine, fellows in adolescent medicine, a nurse, a social worker, and an educational counselor.

7. The program in Indianapolis, Indiana was composed of several neighborhood-based adolescent clinics which were coordinated through a hospital-based adolescent medicine program. The multidisciplinary staff included an adolescent medicine specialist, fellows in adolescent medicine, nurses, and social workers.

Comparison Clinics

1. The clinics in New Orleans, Louisiana were all located in the largest public general hospital in the city. The hospital was part of a large academic medical center with no special clinics for adolescents. Patients were sampled through a walk-in clinic for all non-emergency cases, and through an obstetrical clinic. The staff included staff physicians, residents, and nurses only.

2. Publicly supported neighborhood health clinics with no special services for adolescents made up this service in St. Louis, Missouri. Adolescents were sampled through pediatric, dental, and obstetrical clinics. The staff included only staff physicians and nurses.

3. This site in Buffalo, New York was composed of general outpatient, emergency, and obstetrical clinics of a Children's Hospital and a hospital-based family practice center. The staff included physicians, nurses, and residents in pediatrics, obstetrics-gynecology, and family practice.

APPENDIX B

Risk Factors	Definitions
Pregnancy	Pregnant one or more times.
Use of Weapon	Threatened anyone with a knife or gun or any kind of weapon such as a pick, soda bottle, or something else.
Physical Fights	• Been in physical fights, *or* • Hurt someone badly in a fight, *or* • Taken things from other people by purse-snatching, holding them up, or threatening them.
Legal Problems	Been in trouble with the police or a juvenile officer.
Runaway	Run away overnight or longer from the place where living.
Contraceptive Needs	If had sex *and*: • respondent and partner do not use birth control most of the time, *or* • withdrawal is one type of birth control used.
Regular Tobacco Use	Smoked cigarettes, cigars, or pipes; chewed tobacco; or used snuff every day for a month or more.
Heavy Alcohol/Drug Use	• Drank four or more glasses/drinks of beer/wine/liquor at one time, *or* • Averaged drinking more than once a week or for short concentrated periods over the last year, *or* • Used a drug more than once a week or for short concentrated periods over the last year.

continued

APPENDIX B continued

Risk Factors	Definitions
Suicidal Behavior	Attempted suicide.
Hopelessness	• During a period of feeling blue or depressed (defined as: 1) two weeks or more during which respondent felt sad, blue, depressed, and lost interest and pleasure in things he/she cared about and enjoyed; *or* 2) two years or more when respondent felt sad or depressed almost all the time), work at school, at home, or on the job suffered, *or* • A period of two weeks or more when life felt hopeless or pointless.
School Drop Out	Not in school; highest grade completed was less than 12th.

1988—A Landmark Year for State AIDS Legislation

A detailed legislative review of AIDS-related laws from the 1988 state legislative sessions show that out of 700 AIDS-specific bills introduced in 42 states, a total of 136 laws were passed in 36 states. Six state legislatures were not in session last year. The review, published by the AIDS Policy Center of the Intergovernmental Health Policy Project, found the 1988 legislation to be more comprehensive than in previous years. A series of omnibus laws address controversial and often conflicting policy issues: adding anti-discrimination provisions; amending public health control laws; developing informed consent and confidentiality provisions; and adding testing requirements for special populations or special situations.

Few laws concerning mandatory testing and reporting, contact tracing, quarantine and criminal sanctions were actually passed, although many were introduced. States tended to reject broad measures calling for mandatory testing of the general public and continued to emphasize voluntary testing and counseling, based on written, informed consent. Twenty-four states adopted measures requiring reporting of HIV-positive test results, including "identifiers" (usually a name and address) in at least some situations. However, most states also provide for anonymous testing. In four-fifths of the states, some form of anonymous testing is still available; only eight states have no option for anonymous testing.

During 1988, 27 states strengthened confidentiality provisions in existing communicable or sexually transmittable disease laws to cover test information or passed new laws to provide explicit confidentiality for HIV records.

Whether physicians have a responsibility or duty to inform the spouse or sexual partners of HIV-infected patients of their potential for exposure was addressed in laws in 10 states which now authorize a "discretion to warn."

A number of other major areas were addressed by the states, including voluntary partner notification, non-discrimination laws, restrictions on use of blood tests by insurance companies, and other related matters. Psychoactive Drug Use in a General Population Sample, Sweden: Correlates with Perceived Health, Psychiatric Diagnoses, and Mortality in an Automated Record-Linkage Study

CHRISTER ALLGULANDER, MD

Abstract: Three person-based computer files were linked to provide a data-set of a random sample of 32,679 Swedes, drawn for interviews regarding perceived health, socioeconomic conditions, and psychoactive drug use. All diagnoses from inpatient psychiatric care in the sample during a 15-year period and the causes of death after the sampling point were combined with the interview responses. Among those admitted for inpatient psychiatric care, substance abuse was an infrequent diagnosis; the majority of schizophrenics and of those with an affective disorder appeared not to medicate regularly; survey non-responders had higher rates of mental disorders than responders. Drug use correlated with both subjective and objective measures of mental ill health. The rate of prescription drug abuse was low. Automated record-linkage is a feasible method to generate hypotheses about mental health in the general population. (*Am J Public Health* 1989; 79:1006–1010.)

Introduction

Psychiatric morbidity in general population samples has been surveyed to elucidate rates using lay and professional interviewers,[1,2] prognosis by computer-analyzed questionnaires,[3] and drug treatment of symptoms and diagnoses.[4–7] Correlates between psychoactive drug treatment and social and demographic conditions have also been investigated using pharmacy records,[8] health survey interviews,[9–13] personality inventory,[14] and insurance enrollment questionnaire.[15,16]

The purpose of this study was to describe the characteristics of persons reporting regular psychoactive drug use based on a large interview sample of the general Swedish population, and national psychiatric inpatient and cause-of-death registers, using automated record-linkage of three person-based computer files.

Methods

Four different random samples of the entire Swedish population 16–74 years old were interviewed in the Survey of Living Conditions in 1975, 1977, 1980, and 1981 (see Appendix for details). A total of 32,679 individuals were sampled, representing an average population of 5.8 million Swedes. Of these, 26,952 were interviewed; 5,727 (17.5 per cent) were not interviewed, due to refusals (11 per cent), being unavailable (2 per cent), ill (0.4 per cent), or institutionalized (0.3 per cent). We selected 20 appropriate questions for study (Table 1).

By means of the personal identification numbers, we matched the 32,679 individuals with 1.7 million cases of the national psychiatric inpatient case register for the period 1969–83. The ICD-8 diagnoses, slightly modified in Sweden, were grouped into ten nosological categories. A total of 1,765 sampled individuals had been discharged with psychiatric diagnoses during this 15-year period. Matching errors based on personal identification numbers, were estimated at <2 per cent.

The national Cause-of-Death Register was also scanned. After the sampling point and up to 1985, 1,759 individuals had died. Their underlying causes of death by the ICD-8 classification were retrieved, including definite suicides (E950–959) and deaths where suicide could not be determined with certainty (E980–989). No matching errors occurred.

These data were merged in a new file using the personal identification numbers, which were then removed, to eliminate the identifications. Permission to match these registries was given by the Security Council of Statistics Sweden, the National Board of Health and Welfare, the Data Inspection Board, and the Ethical Review Committee of the Department of Social Welfare, thus meeting with regulatory requirements and suggested ethical practice.

Subgroup characteristics displayed in Tables were analyzed by multiple logistic regression, using the CATMOD procedure in SAS.[17] The dependent variable was either reported regular psychoactive drug use among men and women, respectively, or no or occasional psychoactive drug use among those reporting severe anxiety. Clinically relevant variables were chosen to avoid confounding. To study possible overlap of predictive power and confounding between key variables, the models were repeated without three variables (long-standing illness, disability or infirmity, long-standing nervous symptoms and regular medical treatment). To find "false positive" correlations, models were run also on those reporting good health. Odds ratios and confidence intervals are given for all variables in the models.[18]

Results

The Interview Sample

Regular psychoactive drug use, including prescribed sedatives, neuroleptics, lithium and antidepressants but not hypnotics, was reported by 1.6 per cent of the men and 2.9 per cent of the women (Table 1). The high proportion of elderly among drug users reflects the higher rates of somatic and psychiatric diseases and symptoms, and also concomitant use of analgesics and cardiovascular drugs. The social constrictions may have been related to both age and to poor health: about half the drug users had reduced work capacity, and about one in four had reduced physical mobility.

Only a third of the psychoactive drug users also used hypnotics regularly, although more than half had current sleep problems or fatigue. Nearly all reported some long-standing illness, disability or infirmity, and were receiving

*by age group 16–30, 31–50, 51–74.
Multiple logistic regression models with psychoactive drug use as the dependent variable, by sex. Odds ratios and 95% confidence intervals.

regular medical treatment. Inpatient psychiatric treatment during the 15-year study period was recorded among 44 per cent of the men and 34 per cent of the women who reported regular psychoactive drug use, compared to 5 per cent and 4.4 per cent of all responders. An inpatient psychiatric diagnosis of substance abuse was on record for 17 per cent of the men and 4 per cent of the women, compared to 2.5 per cent and 0.6 per cent of all responders.

In the multiple regression models, the interview and register variables most strongly associated with regular psychoactive drug use were long-standing nervous symptoms, regular medical treatment, regular use of hypnotics and prescribed analgesics and inpatient psychiatric treatment (Table 1).

Anxious Responders

Approximately half of the entire sample was asked a separate question about anxiety in the last two weeks in the 1980 and 1981 interviews. Only 31 per cent of those with severe anxiety reported regular psychoactive drug use; these were primarily women. Those women reporting severe anxiety but no/occasional psychoactive drug use can be characterized as: living alone in urban areas, low income and poorly educated with reduced work capacity, few or no neighborly contacts, and a variety of psychosomatic symptoms (insomnia, fatigue, headaches and nervous symptoms) (Table 2). Three-fourths of the women reported long-standing illness, disability or infirmity (Table 2); most of them suffered from fatigue and insomnia; 21 per cent had been treated in inpatient psychiatric care during the 15-year study period. In another such model of 107 anxious responders who had regular drug treatment, a similar profile was not found.*

Psychiatric Inpatients

The 1,765 psychiatric inpatients were analyzed by their interview responses regarding drug use and symptoms. Only 37 per cent of the drug users had been psychiatric inpatients. Neurotic disorder was the most frequent diagnosis among regular users (Table 3). Of those 137 responders who had received an inpatient psychiatric diagnosis of *schizophrenia*, 64 per cent reported long-standing nervous symptoms, but only 34 per cent reported regular psychoactive drug use. Of those 119 with a diagnosis of affective disorder, only 33 per cent reported regular drug use, yet 42 per cent reported long-standing nervous symptoms.

*Data available on request to author.

*by age group 16–30, 31–50, 51–74.

Multiple logistic regression model with no or occasional drug use as the dependent variable: Odds ratios and 95% confidence intervals.

Sixty-three of 323 psychiatric diagnoses (20 per cent) among the psychoactive drug users were for substance abuse disorders, compared to 338 of the 1,025 diagnoses (33 per cent) among all survey respondents. Only 38 individuals had been admitted to inpatient psychiatric care for prescription drug abuse; 19 of them had a concomitant diagnosis of alcohol abuse, and two of street-drug abuse. Thus, only 17 individuals had been admitted for primary prescription drug abuse, a rate of 3.5 per 100,000 person years.

Representativity, Validity and Confounding

Non-responders had received inpatient psychiatric care twice as often as responders (8.1 vs 4.7 per cent) and had higher rates of most psychiatric disorders (Table 3). Since current illness was the reason for non-participation in the interviews in <1 per cent, the difference cannot be explained by illness at the time of the interview. The non-responders also had a higher suicide rate (22/5,727 vs 59/26,952).

The internal validity of the regression models was tested by creating models for those who reported no major health problems (7,337 men and 7,377 women, 55 per cent of all responders). Only two inverted associations to good health (to fatigue and regular hypnotic drug use) among men were found. Thus, the models appear to reflect actual associations between the independent variables and drug use.

TABLE 3—Psychiatric Diagnoses in Inpatient Care per 1,000 Persons among Sample Responders, Non-responders, and Regular Psychoactive Drug Users 1969-83

Diagnoses	All Responders n = 26,952	Non-responders n = 5,727	Regular Drug Users n = 595
Neurosis (n =716)	20.1	30.4	176.5
Alcoholism (n =519)	13.7	26.2	73.9
Unspecified psychosis (n =202)	5.4	9.8	60.5
Schizophrenic psychosis (n =180)	4.3	11.0	65.5
Personality disorder (n =166)	4.6	7.3	45.4
Affective disorder (n =150)	4.4	5.4	65.5
Street-drug abuse (n =100)	2.5	5.8	20.2
Dementia (n =59)	1.3	4.2	15.1
Prescription drug abuse (n =38)	0.9	2.4	11.2
Other psychiatric diagnoses (n =39)	0.8	3.1	8.4

The same person may appear with more than one diagnosis

The external validity of our data appeared satisfactory when compared to the rates of major psychiatric disorders reported in other studies[1,19] and to the disease spectrum among psychoactive drug users.[4-7] The validity of symptoms of fatigue, insomnia, nervousness, and depression reported to lay interviewers was similar to that in another Swedish health survey.[3] In a Finnish health interview survey by nurses, 20 per cent of those reporting both a chronic illness and psychological distress used psychoactive drugs, vs 5 per cent of those who had only psychiatric symptoms.[10] In multiple logistic regression models, the Finnish investigators showed that chronic morbidity, psychiatric symptoms, and physician visits were the best predictors of psychoactive drug use, age being of importance only among women. Our data point to the same conclusion.

When we repeated the regression models without three potentially confounding variables (long-standing nervous symptoms, long-standing illness, disability or infirmity, and regular medical treatment), new associations were noted among drug-using men (age, insomnia, fatigue, being single, having a reduced physical mobility, and lacking neighbor relations), and among drug-using women (fatigue).*

Two of our findings appeared to be spurious. The reduced odds of substance abuse in male drug-takers may be the result of competition with other independent variables. The male substance abusers scored high on a number of indicators of poor health, compared to all males (data to be published). The contribution of those variables (reduced work capacity in 28 per cent of male substance abusers, long-standing nervous symptoms 14 per cent, insomnia 32 per cent, regular psychoactive drug use 11 per cent) to the model reduced the odds ratio of substance abuse, in spite of the fact that 17 per cent of regular psychoactive drug users were also substance abusers. The reduced odds of suicide in female drug-takers may have a similar explanation.

Mortality

In those using psychoactive drugs regularly, there were 79 deaths against 46 expected (95% confidence interval of the difference 15, 51). Among those who reported severe anxiety

there were 23 deaths vs eight expected (95% CI of difference 5, 25). Those diagnosed with schizophrenia had an excess of 19 deaths vs eight expected (95% CI of difference 2, 20), neurotic disorders 34 vs 18 expected (95% CI of difference 4, 28), and with affective disorders there were 11 deaths vs seven expected (95% CI of difference −3, 11).

Among the natural causes of death, only endocrine disorders were more common than expected among the regular psychoactive drug users.

Discussion

Automated record-linkage was used in this study to describe a profile of those in the general population who receive regular treatment with psychoactive drugs. To study causation, longitudinal data are preferred, yet cross-sectional data may contribute to the formulation of explanatory hypotheses for further study.[11]

In addition to the ambiguities inherent in health surveys, the psychoactive drugs could not be subdivided into therapeutic categories. Inpatient psychiatric treatment prior to 1969 as well as any outpatient psychiatric treatment could not be studied. Yet the findings derived with this method appear to be both externally and internally valid. Considering the chronic course of many psychiatric disorders, it is disconcerting that only 42 per cent of those with long-standing nervous symptoms and only one-third of those with schizophrenia were medicating regularly. Another concern is that those who reported severe anxiety, but no or occasional psychoactive drug use were primarily lower-educated women in urban areas, socially isolated and with several symptoms of mental ill health. One wonders whether or not they are in outpatient treatment.

For those who had received psychiatric inpatient treatment, substance abuse was less frequent among drug-users than non-drug-users. One tentative explanation is that pharmacotherapy in patients properly evaluated reduces the risk of substance abuse. The number of prescription drug abusers was small in this sample, indicating that the risk of iatrogenic psychoactive drug abuse leading to inpatient psychiatric care is less common than is generally believed.[21] The assumptions about psychoactive drug overmedication of Swedish general practice patients has also not been shown to hold.[22,23]

Among those admitted for inpatient psychiatric care, the rates of different psychiatric disorders were higher in the non-responders to the health survey, and this was not due to current illness. Although based only on hospital admissions, interpretations of health surveys should consider this source of bias in determining rates of psychiatric morbidity in the general population, and their effects on social drift and suicide. Future investigators will also have to cope with the increasing reluctance among the public on privacy grounds to being scrutinized and recorded in computer files.

ACKNOWLEDGMENTS

Scientific comments were made by Professor Lee N. Robins, John E. Helzer, and Edward C. Senay, and by Associate Professor Peter Allebeck. Per Näsman, BSc, and Martin Ribe, PhD, skillfully performed the statistical programming and analyses. The data were made available by Professor Sten Johansson, Dr. Börje Lassenius and Ms. Vesta Keiland. The staff of Statistics Sweden gave advice and logistic support in the analysis (Ingrid Sjöberg, BSc, Per-Olof Fredriksson, BSc, and Gudrun Lindberg, BSc). This research was supported by grants from the Swedish Ministry for Health and Social Affairs, Commission for Social Research (no. D87/65:1), and the Söderström-Königska Foundation.

APPENDIX

Swedish Survey of Living Conditions

Statistics Sweden regularly conducts interviews in randomized samples of the Swedish population, similar to the surveys initiated in the United States on the basis of the Health Survey Act 1956. The purpose is to provide the government with a decision-base on socioeconomic conditions, perceived health, and health care utilization. The samples are drawn from the Register of the Total Population, including institutionalized persons, excluding those interviewed in previous samples. Subjects are interviewed by about 200 trained interviewers for one hour at their location; 2–3 per cent are interviewed through a key relative, and 10 per cent over the telephone. Errors in coverage and computational procedures are practically negligible. For the samples in this study, the non-response rate due to refusals was 18.8 per cent in 1975, 19.3 per cent in 1977, 13.7 per cent in 1980, and 13.5 per cent in 1981.

Included in the interview are basic demographic data, housing, leisure facilities, access to public transport, children, general health, medical disorders by the World Health Organization classification system, physical and occupational handicaps, health care utilization, smoking, work conditions, education, unemployment, interest in politics and mass media, relations with neighbors and relatives.

The dependent variable in this study was based on the following questions to the responders: "Have you *in the last two weeks* used any of the following medicines?" A number of categories were listed, such as cough medicines, antibiotics, laxatives, etc. Responses were tabulated as follows:

Tranquilizers (drugs to calm your nerves)	n	% Interviewed
Yes, regularly	595	2.2
Yes, occasionally	750	2.8
No	24,976	92.5
Do not know	36	0.1
No answer	634	2.3
Total	26,991	100

The drugs are not exemplified by brand names, nor is "regular" defined beyond current (last two weeks) and regular use as perceived by the responder.

Personal identification numbers are given to all persons living in Sweden. This unique means of identifying an individual can be used to combine person-based data from different computer files. There are national registries for inpatient care, congenital malformations, cancer, causes of death etc.

Nurses Working in the Field of AIDS to be Honored; Nominations Invited

October 1989 will be observed as AIDS Awareness and Prevention Month. One of the ways in which the US Public Health Service will participate is to honor nurses in America who have exhibited courage and compassion for people with AIDS and HIV infection in the exercise of their professional duties. Assistant Secretary for Health James O. Mason, MD, DrPH, will present Awards to 10 deserving nurses.

In order to identify these 10 recipients, Dr. Mason has invited nominations from various organizations. The deadline for such nominations is August 15, 1989.

The broad criteria established for these awards is that the individual must be a Registered Nurse with a minimum of three years' experience as a direct care provider for people with AIDS, either as part of his or her usual job or as a volunteer. Although the awards are not limited to US citizens, the work thus recognized must have been performed within the territorial US. Extra consideration will be given for participation in such things as community involvement/outreach programs, recruitment, special care programs, professional organization involvement, publications, and other innovative efforts to ensure care for people with AIDS.

An awards ceremony will be held at the Hubert H. Humphrey Building in Washington, DC on October 4, 1989 at which Dr. Mason will present the awards. PHS will provide transportation for the recipients.

Letters of nomination for the awards, along with a curriculum vitae and a photograph of the nominee, should be sent to: Jim Brown, Director, News Division, Office of Communications, USPHS, 200 Independence Avenue, SW, Room 717H, Washington, DC 20201. Tel: (212) 245-6867.

Alcohol Consumption and Problem Drinking in White Male Veterans and Nonveterans

MARGARET S. RICHARDS, PHD, JACK GOLDBERG, PHD, MIRIAM B. RODIN, MD, PHD, AND ROBERT J. ANDERSON, PHD

Abstract: The relation between veteran status and 15 indicators of alcohol consumption and problem drinking is examined using data from the 1977, 1983, and 1985 National Health Interview Surveys conducted by the National Center for Health Statistics. After simultaneous adjustment for age, region of the US, urbanization, ethnicity, marital status, education, and income, a greater proportion of White male veterans than White male nonveterans were heavy drinkers and a smaller proportion were abstainers. This association appeared in all three survey years; further, veterans consistently reported a high daily consumption level (the equivalent of approximately six bottles of beer, five glasses of wine, or four mixed drinks) compared to nonveterans.

Among White male veterans, 6.9 percent reported family or marital problems and 13.9 percent reported motor vehicle crashes or violations compared to 4.4 percent and 8.9 percent, respectively, among nonveterans. The same pattern was observed for lifetime prevalences of alcoholism (veterans have nearly two and a half times the lifetime prevalence of nonveterans), cirrhosis of the liver, and unspecified alcohol-related problems. (*Am J Public Health* 1989; 79: 1011–1015.)

Introduction

Although there have been numerous studies of alcohol use by men who served in the armed forces in Vietnam, there are few studies of alcohol use among men with other military service experience. A study of men on active duty in stateside Army installations[1] revealed that both officers and enlisted men had larger proportions of heavy drinkers than the civilian population, even after adjustment for age and education. Problem drinking was more common among enlisted men than civilians, an effect which was not apparent among the officers. Cahalan, *et al*, suggested that, ". . . there is something about the Army that fosters drinking over and above those forces at work in the society at large."[1]

In contrast, Polich[2] examined problem drinking in men on active duty in the Army, Navy, and Air Force. Although the problem drinking rate for the military group was somewhat higher than the civilian group, the difference was substantially reduced by adjustment for age, education, and marital status.

A more salient issue is the post-military use of alcohol. Drinking behaviors acquired during military service may persist well into civilian life and can affect an individual's physical or psychosocial well-being. A large body of data suggests that there is a high prevalence of alcohol problems and alcoholism among Veterans Administration patients.[3–6] These "rate-under-treatment studies" are problematic, however, because of the unique characteristics of help-seeking veterans. Boscarino[7,8] surveyed alcohol consumption in a random sample of veterans and nonveterans and concluded that the higher prevalence of heavy drinkers among veterans is accounted for by differences in nine demographic characteristics: sex, age, race, region of United States, urbanization, ethnicity, marital status, education, and income.

The variable conclusions of the Cahalan, *et al*, Polich, and Boscarino surveys may be in part due to differences in the populations surveyed (men on active duty vs veterans), the outcomes measured (excessive consumption vs problem drinking vs some construct of the two), and the extent and type of demographic adjustment performed (single variable adjustment vs multivariable adjustment). The purpose of this investigation is to examine alcohol consumption and problem drinking in White male veterans and nonveterans who participated in the National Health Interview Survey Supplements of 1977, 1983, and 1985. To test the hypothesis that White male veterans drink more than White male nonveterans and experience more alcohol-related adverse consequences, we examined 15 alcohol use outcomes after adjustment for demographic characteristics.

Methods

Sources of Data

The National Health Interview Survey (NHIS) is an annual household survey by the National Center for Health Statistics (NCHS) involving personal interviews of a nationwide sample of the civilian, noninstitutionalized population of the United States. The sampling plan of the survey follows a multistage probability design which ensures that these households are representative of the target population. Details of the NHIS are presented fully elsewhere.[9]

On an irregular basis, the NCHS adds special supplemental components to the core NHIS questionnaire. The supplemental questionnaires administered in 1977, 1983, and 1985 elicited information on alcohol use. Unlike the core questionnaire which relies on cost-effective proxy responses, all three of these supplements use direct self-reporting to obtain more accurate information.

Measures of Veteran Status

Veteran status is ascertained in the core NHIS questionnaire in 1977, 1983, and 1985. Using computer tapes for the three interview years, we identified male veterans and male nonveterans to obtain the following sample sizes: in 1977, 4,005 veterans and 5,845 nonveterans; in 1983, 2,901 veterans and 6,004 nonveterans; and in 1985, 4,079 veterans and 8,998 nonveterans. However, we limited our selection to those veterans and nonveterans with complete data for the outcome variable and the seven covariates (age, region of the United States, urbanization, ethnicity, marital status, education, and income) used in the multivariable adjustment procedure. Our definition of complete data led to the exclusion of such survey responses as "unknown," "refused," or "other." This selection reduced the 1977 sample by 28

This paper, submitted to the Journal July 19, 1988, was revised and accepted for publication December 21, 1988.

© 1989 American Journal of Public Health 0090-0036/89$1.50

percent, the 1983 sample by 13 percent and the 1985 sample by 11 percent. We further restricted the sample to White male veterans and nonveterans, recognizing that persons of other races tend to have different drinking patterns than Whites but contribute little in the way of sample size. Thus, the final sample sizes for the three interview years are: 1977, 2,707 veterans and 3,704 nonveterans; 1983, 2,326 veterans and 4,590 nonveterans; and 1985, 3,181 veterans and 6,749 nonveterans.

Measures of Alcohol Consumption

From the alcohol data included on the NHIS supplements we selected 15 dependent variables which provide a concise description of drinking behavior. The 15 variables can be grouped into two categories representative of alcohol use: level of consumption, and adverse consequences. The variables which delineate adverse consequences of alcohol use include five adverse social consequences and seven adverse health consequences (see Appendix A). Owing to the varying amount of detail in each supplement year with regard to alcohol use questions, these 15 outcomes are associated with data from one, two, or three supplement years as shown in Appendix A. The differences between these measures according to survey year are discussed in Appendix B.

Statistical Analysis

The statistical analysis of the relationship between veteran status and the 15 alcohol use outcomes employs a logistic regression procedure to produce predicted proportions of veterans and nonveterans in each category of the dependent variable. If the outcome is ordinal, a modification of the logistic model for dichotomous outcomes is used.[10] Although it is possible to conduct these analyses using the sampling weights provided by NCHS, we chose to perform an unweighted analysis owing to the fact that our comparison category (veteran vs nonveteran) is not influenced by sampling.

Logistic models for each of the 15 outcomes are constructed to examine the effect of veteran status. These models include seven potential confounders: age, region of the US, urbanization, ethnicity, marital status, education, and income. By examining the adjusted proportions we can determine what drinking behaviors, if any, are associated with prior military service above and beyond the more general societal influences. The adjusted proportions are produced using a covariance adjustment method.[11,12]

Results

Levels of Alcohol Consumption

The top portion of Table 1 presents the relationship between veteran status and drinking level after adjusting for age, region of the US, urbanization, ethnicity, marital status, education, and income. In each supplement year, a positive association is observed between drinking level and veteran status. Among nonveterans, there are more abstainers and light drinkers whereas among veterans, there are more moderate and heavy drinkers. The proportion of heavy drinkers among veterans consistently exceeds the proportion of heavy drinkers among nonveterans by 2 to 6 percent.

As with drinking level, a positive association between high alcohol consumption and veteran status is evident in all three survey years (Table 1). This association is most pronounced in 1983, where the proportion of veteran high consumers is nearly twice that of nonveteran high consumers. If the 1983 high consumer were a single beverage drinker, that individual would report a daily intake equivalent to approximately six bottles of beer, five glasses of wine, or four mixed drinks.

In all survey years, a larger proportion of nonveterans than veterans report that they have not had five or more drinks in one day during the past 12 months. Conversely,

TABLE 1—Levels of Alcohol Consumption in White Male Veterans and Nonveterans: Drinking Level, High Consumption and Number of Heavy Consumption Days[a]

	Interview Year and Veteran Status

[a]Percentages are adjusted for age, region of the US, urbanization, ethnicity, marital status, education, and income. These variables are described in detail in Appendix A.
[b]Measured on the entire population of veterans and nonveterans.
[c]Measured on current drinkers only.
[d]Measured on current and noncurrent drinkers. Note that this information was not obtained in the 1977 interview.

TABLE 2—Adverse Consequences of Alcohol Consumption in White Male Veterans and Nonveterans: 1983 NHIS Lifetime Social Consequences[a]

Social Consequences	Veteran Status	
	% Veterans	% Nonveterans
Family or Marital Problems	(n = 2,064)	(n = 3,739)
no problems	93.1	95.6
1 or more problems	6.9	4.4
Motor Vehicle Crash or Violation	(n = 2,059)	(n = 3,734)
no incidents	86.1	91.1
1 or more incidents	13.9	8.9
Job Problems	(n = 2,063)	(n = 3,739)
no problems	97.9	98.2
1 or more problems	2.1	1.8
Injury	(n = 2,063)	(n = 3,737)
no injuries	95.6	95.9
1 or more injuries	4.4	4.1
Social Consequences Score	(n = 2,059)	(n = 3,729)
0 problems	79.6	85.7
1–2 problems	14.2	10.1
≥ 3 problems	6.2	4.2

[a]Percentages are adjusted for age, region of the US, urbanization, ethnicity, marital status, education, and income. These variables are measured on current, noncurrent, and former drinkers, and are described in detail in Appendix A.

veterans are more likely than nonveterans to report 12 or more heavy consumption days in the past year (Table 1).

Adverse Consequences of Alcohol Consumption

The relation of veteran status and lifetime adverse social consequences of alcohol consumption adjusted for demographic factors is presented in Table 2. Among veterans, the proportion of men experiencing family and marital problems is one and a half times the size of the comparable proportion among nonveterans; a similar pattern is observed for alcohol-related motor vehicle crashes and violations. Veteran status appears to be unrelated to injury. The additive social consequences score is elevated for veterans.

TABLE 3—Adverse Consequences of Alcohol Consumption in White Male Veterans and Nonveterans: 1983 NHIS Lifetime Health Consequences[a]

Health Consequences	Veteran Status	
	% Veterans	% Nonveterans
Alcoholism	(n = 2,067)	(n = 3,741)

0 problems	88.2	90.2
1–2 problems	9.1	7.6
≥ 3 problems	2.7	2.2

[a]These variables are measured on current, noncurrent and former drinkers, and are described in detail in Appendix A. Percentages are adjusted for age, region of the US, urbanization, ethnicity, marital status, education, and income.

Table 3 presents the relationship between veteran status and lifetime adverse health consequences of alcohol consumption after adjusting for demographic factors. These results are not as consistent as those for the social consequences, involving fewer events and less stable estimates. Event categories involving less than five cases are not reported. Compared to nonveterans, veterans report an increased lifetime prevalence of alcoholism, cirrhosis of the liver, unspecified alcohol-related health problems, and all health consequences combined. Of these four categories, the alcoholism outcome is the most compelling: veterans have nearly two and a half times the lifetime prevalence of alcoholism compared to nonveterans.

Discussion

A fundamental concern in cross-sectional studies of alcohol use is the issue of adequate control for confounding factors. Certainly our adjustment for seven demographic variables cannot be termed exhaustive for it does not include any pre-service (e.g., parents' drinking habits) or in-service (e.g., combat exposure) variables.

An informative comparison can be made between our work and the study by Boscarino.[7] Boscarino examined level of alcohol consumption in a 1975 national probability sample of 3,071 American adults. As with the NHIS survey, veteran status was ascertained by self-report.

Although Boscarino does not provide specific details as to how his ethanol consumption estimate was derived, he does state that it is based on the "quantity and frequency of 'usual' alcoholic beverages consumed in the 30 days preceding the interview." Our 1983 estimate relies on exact quantities and frequencies of each beverage type in the 14 days prior to the interview. Nonetheless, in his unadjusted results for level of consumption, Boscarino found that veterans are significantly more likely than nonveterans to report higher consumption levels.

In the examination of adjusted results, however, our conclusions differ from those of Boscarino. When Boscarino adjusted for sex, race, age, region of the United States, urbanization, ethnicity, marital status, education, and income the excess percent of heavier drinkers among veterans disappeared. Boscarino replicated his 1980 findings using a second survey conducted in 1977 (n = 3,322 adults).[8]

What might explain the discrepancy between Boscarino's and our results? It is unlikely that the divergent results are due to different alcohol consumption measures since both studies use similar measures. However, our analytical procedures for adjustment differ from Boscarino's in several respects. First, Boscarino includes both males and females in his sample. He attempted to adjust for potential confounding by sex using a regression model which included sex as an independent variable. This is a questionable strategy because women (who have very different alcohol consumption levels from men) comprise only 2 percent of Boscarino's veteran sample but approximately 50 percent of the nonveteran sample. We excluded females from our analysis because few females are veterans. Second, Boscarino's data are composed of both Whites and non-Whites and race is included as a dichotomous adjustment factor. Recognizing that the "non-White" group (which includes Blacks, Asians, and other categories) is heterogeneous with respect to alcohol use, we restricted our analysis to Whites. Third, Boscarino's use of

ordinary least squares regression with an ordinal dependent variable is not entirely appropriate. We used a form of logistic regression adapted for ordinal dependent variables. Fourth, one of Boscarino's nominal independent variables (urbanization) was not dummy coded but was left in its original form. The presumption of a linear increase in risk of consumption implied by such coding is questionable. We dichotomized all of the independent variables except for age, education, and income, which were coded ordinally.

The 1988 NHIS supplement includes questions on alcohol use as well as the standard veteran question. When these data become available, it will be possible to determine if some of the associations demonstrated here between veteran status and alcohol use are replicated.

APPENDIX A
Description of Alcohol Use Variables Analyzed

Category	Dependent Variable	Supplement Years Available	Subpopulation Referenced[a]
Level of Consumption	Drinking level[b]	1977, 1983, 1985	Total
	High consumption[c]	1977, 1983, 1985	Current drinkers
	Heavy consumption days[d]	1983, 1985	Current and noncurrent drinkers
Lifetime Adverse Consequences of Alcohol Use	*Social Consequences*	1983	Current, noncurrent, and former drinkers
	Family or marital problems		
	Motor Vehicle crash or violation		
	Job problems		
	Injury		
	Social consequences score[e]		
	Health Consequences	1983	Current, noncurrent, and former drinkers
	Alcoholism		
	Cirrhosis of the liver		
	Unspecified alcohol-related health problem		
	Delirium tremens		
	Blackouts		
	Fatty liver		
	Health consequences score[f]		

a) The total population includes current drinkers, noncurrent drinkers, former drinkers, and abstainers. Current drinkers report having had a drink in the two weeks preceding the interview whereas noncurrent drinkers had their last drink more than two weeks (but less than a year) prior to the interview. A former drinker's last drink was more than a year before the interview; an abstainer has had less than 12 drinks in any one year of his life.

b) Drinking level is based on a composite measure which reflects the average daily ethanol consumption (ADEC) from all alcoholic beverages (beer, wine, and liquor) combined. ADEC is calculated from the Quantity/Frequency (Q/F) items of the questionnaires and then categorized to obtain drinking level. The levels correspond to NIAAA guidelines where: abstainers average 0.0 ounces ethanol daily; light drinkers, 0.01–0.21 ounces ethanol daily; moderate drinkers, 0.22–0.99 ounces ethanol daily; and heavy drinkers, 1.00 or more ounces of ethanol daily.

c) High Consumption is also based on the composite measure ADEC. High consumption is simply the number of ounces of ethanol corresponding to the upper fifth percentile of the ADEC distribution for veteran and nonveteran drinkers combined. These "cutoff" levels of consumption are specific for interview year and represent the observed extreme among current drinkers. In 1977, this extreme is 1.96 ounces of ethanol per day. In 1983, it is 2.88 ounces of ethanol per day, and in 1985, 2.14 ounces of ethanol per day.

By converting ounces of ethanol to ounces of beer, wine, or liquor, it is possible to determine how many drinks constitute high consumption.[13] For example, high consumption in 1983 corresponds to six or more beers per day:

$$\frac{1.00 \text{ oz. beer}}{0.04 \text{ oz. ethanol}} \times \frac{1 \text{ bottle}}{12 \text{ oz. beer}} \times 2.88 \text{ oz. ethanol/day} = 6.0 \text{ bottles/day}$$

Similar equations can be set up for wine and liquor in the 1983 data set:

$$\frac{1.00 \text{ oz. wine}}{0.15 \text{ oz. ethanol}} \times \frac{1 \text{ glass}}{4 \text{ oz. wine}} \times 2.88 \text{ oz. ethanol/day} = 4.8 \text{ glasses/day}$$

$$\frac{1.00 \text{ oz. liquor}}{0.45 \text{ oz. ethanol}} \times \frac{1 \text{ drink}}{1.5 \text{ oz. liquor}} \times 2.88 \text{ oz. ethanol/day} = 4.3 \text{ drinks/day}$$

These calculations can be repeated for the 1977 and 1985 data sets.

d) The number of heavy consumption days is the number of days in the past year when the respondent reports having consumed five or more alcoholic drinks in one day.

e) This score is a simple summation of the number of social problems (family/marital, motor vehicle crash/violation, job, injury) reported by the respondent. Respondents indicate whether or not they have ever experienced a drinking-related event involving their family or spouse, a motor vehicle crash or violation, their job, or an injury. (For example, the injury question reads, "Have you EVER had an injury related to YOUR drinking?".[5]) An overall score was not computed for a respondent if any problem item was missing; thus, the sample size for the social consequences score is smaller than the sample sizes associated with the individual problems.

f) This score is a simple summation of the number of health problems (alcoholism, cirrhosis of the liver, unspecified alcohol-related health problem, delirium tremens, blackouts, fatty liver) reported by the respondent. Respondents are asked about the cumulative health effects of alcohol including alcoholism, cirrhosis of the liver, an unspecified alcohol-related health problem, delirium tremens, blackouts, or fatty liver. Unlike the social consequences, the health consequences are not specifically related by the interviewer to alcohol use; rather, respondents are simply asked if they have ever had the condition. We chose from a list only those conditions which are the prima facie endpoints of chronic, excessive alcohol use. As with the health consequences score, the sample size for the social consequences score is smaller than the sample sizes associated with the individual problems.

APPENDIX B
Details of the Differences in the 1977, 1983, and 1985 NHIS Supplemental Interviews

Definitions of Drinkers

The 1983 questionnaire includes groups of questions written especially for subjects who currently drink, subjects who are not currently drinking, former drinkers, and abstainers. Current drinkers report having had a drink in the two weeks preceding the interview whereas noncurrent drinkers had their last drink more than two weeks (but less than a year) prior to the interview. A former drinker's last drink was more than a year before the interview; an abstainer has had less than 12 drinks in any one year of his life.

In the 1977 and 1985 questionnaires, however, the majority of the alcohol questions are asked of current (and occasionally noncurrent) drinkers only. The subpopulation referenced for each variable in Appendix A represents not only that variable's availability for a specific type of drinker but an attempt on our part to maximize the interpretability and consistency of that measure across supplement year. In general, the level of consumption variables measure "current" drinking or, in the case of heavy consumption days, drinking over the past year. The adverse consequence variables, on the other hand, refer to drinking problems experienced over a lifetime.

Definition of Alcohol Use Measures

Drinking level and ADEC are generated by NCHS in the 1983 data but must be calculated for the 1977[14] and 1985[15] data sets. Moreover, it should be noted that the 1977 and 1985 measures of drinking level are only approximations of the 1983 measure. For example, in 1977 respondents were asked if they drank beer (or wine or liquor) "never," "occasionally," "once or twice a week," "more than twice a week," or with some other frequency. This is in contrast to the 1983 frequency question which requires the respondent to count the number of days out of the last 14 in which beer (or wine or liquor) was consumed. The 1985 Quantity/Frequency questions ask not about specific beverages but about "drinks" in general; an assumption about the ethanol content of an unspecified drink must then be made.[15] Thus, an examination of drinking level or high consumption across supplement year must be done with caution. The heavy consumption days question (asked only of 1983 and 1985 respondents) is consistent between questionnaires, however.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Gerry E. Hendershot and Nelma B. Keen of the National Center for Health Statistics, Division of Health Interview Statistics, for their invaluable assistance in preparing the data tapes for analysis. International Conference: Public Health and Sexual Transmission of Diseases

An international meeting—Public Health and the Sexual Transmission of Diseases: Directions for Future Research and Health Policy—is being organized to take place in Chamonix, France, April 23–25, 1990. Limited to only 140 participants, the proposed scientific meeting will focus on those STDs of major public health importance: infections due to gonococcus and chlamydia trachomatis, papilloma virus, and human immunodeficiency virus (HIV). The aim of the meeting is to study these diseases from a public health perspective, adopting a common approach to the problem of AIDS (acquired immunodeficiency syndrome) or other STDs. Focusing on the relation between behavior and the development of STDs, including AIDS, and on preventive measures to reduce the incidence and restrict the consequences of these diseases, the meeting will include four plenary sessions:

- STDs: A challenge to public health
- STDs: A challenge to society
- Individual and group behavior and the spread of STD
- STD prevention: Strategies and evaluation

A free paper session and two round tables, "Directions for future research" and "Recommendations for future public health initiatives," will complete the program.

A Case-Control Study of Pancreatic Cancer and Cigarettes, Alcohol, Coffee and Diet

GEARY W. OLSEN, DVM, PHD, JACK S. MANDEL, PHD, ROBERT W. GIBSON, PHD, LEE W. WATTENBERG, MD, AND LEONARD M. SCHUMAN, MD

Abstract: A pancreatic cancer case-control study was conducted in the Minneapolis-St. Paul area. Family members were interviewed about the subject's usage of cigarettes, alcohol, coffee, and other dietary factors in the two years prior to death (cases, n = 212) or prior to interview (controls, n = 220). The adjusted odds ratio for two packs or more of cigarettes per day was 3.92 (95% CI = 1.18, 13.01) and four or more drinks per day OR 2.69 (95% CI = 1.00, 7.27). Coffee was not a risk factor (seven cups or more per day; OR 0.58 (95% CI = 0.27, 1.27). A positive trend was observed for beef and pork consumption, and a negative trend from cruciferous vegetables. (*Am J Public Health* 1989; 79:1016–1019.)

Introduction

Cigarette smoking is the only currently known etiologic factor for pancreatic cancer.[1] While some epidemiologic studies have shown a positive association between alcohol consumption and pancreatic cancer,[2–4] most have not.[5–11] A positive association between pancreatic cancer and coffee consumption was reported in one study,[5] but was not substantiated by other studies.[6–10] Four case-control studies have reported inconsistent findings regarding meat and vegetable consumption.[7–10] The present case-control study was designed to evaluate further the role of cigarettes, alcohol, and coffee as well as to explore other dietary factors.

Methods

Cases were White males ages 40 to 84 whose deaths occurred between January 1, 1980 and June 30, 1983 with pancreatic cancer (exocrine only) listed on the death certificate; place of residence at the time of death was within the seven-county Minneapolis-St. Paul area.

There were 262 pancreas-identified cancer deaths. An informant was located for 250 cases and 212 (84.8 percent) were interviewed. Of those interviewed, 140 cases (66.0 percent) had pathological confirmation.

Population-based controls were White males, ages 40–84, ascertained through random digit dialing and frequency matched within five year groups. A total of 94.2 percent of all households screened provided data.[12] The following are the percentages (in parentheses) of eligible controls whose respondents agreed to participate in the study: less than 60 years of age (80.2), ages 60–64 (82.2), 65–69 (92.6), 70–74 (72.7), 75 and older (69.5).

The widow (case) or spouse (control) was interviewed at home. If unavailable, the next closest relative (e.g., daughter) was sought. The spouse was the primary respondent for 73 percent of the cases and 92 percent of the controls. The subject's wife or daughter provided the information for 88 percent of the cases and 97 percent of the controls.

Questions on smoking, drinking, and diet pertained to the subject's usage two years prior to death for the cases and two years prior to the interview for the controls. Individual dietary information was obtained by a frequency-of-use questionnaire. Frequency categories ranged from no use to daily use (two or more packs of cigarettes, four or more drinks of beer, wine, or hard liquor, and seven or more cups of coffee). An index of alcohol consumption was computed using the combined frequencies of beer, wine, and hard liquor. In-season and out-of-season consumption was asked for selected vegetables and fruit. Reported are the the monthly consumption indices for beef, pork, poultry, cruciferous vegetables (cabbage, broccoli, brussel sprouts, and cauliflower) and noncruciferous vegetables, fruits and juices, bread and cereals, and dairy products.

Logistic regression was employed to obtain maximum likelihood point estimates and 95 percent confidence intervals of the odds ratio.[13] Odds ratios were adjusted for the potential confounding variables of age, educational status, reported history of diabetes mellitus, cigarettes, alcohol as well as other dietary life-style factors where applicable, i.e., frequency of meat (beef, pork and poultry) and vegetable (cruciferous and noncruciferous) consumption.

Analyses were performed using all cases and only histologically confirmed cases. Since there were no differences, the results are reported for all cases combined. Data were also analyzed and reported separately for all respondents and spouse only respondents.

Results

An increased risk for pancreatic cancer was observed for current cigarette smoking and, to a less extent, smoking duration (Table 1). An index of total alcohol consumption (Table 2) showed a greater than two-fold risk for pancreatic cancer for heavy alcohol consumption (four or more drinks per day), primarily due to heavy beer and hard liquor consumption. There was weakly decreased risk for coffee consumption. A positive trend was observed for the consumption of beef and pork but not poultry (Table 3). Consumption of cruciferous vegetables showed a negative trend but this was not observed with the consumption of noncruciferous vegetables or fruits and juices. Increased risks were associated with dairy products and breads and cereals. However, a strong difference was observed in the consumption of white versus whole wheat bread. The upper quartile

Discussion

The reporting of pancreatic cancer on the death certificate has been shown to be quite accurate.[14] The use of death certificates allowed for the virtually complete ascertainment of all cases in the defined geographic area and justified the use of a population-based control group.

In this study, live rather than deceased controls were selected. The use of deceased controls may introduce a bias since their use of alcohol and cigarettes may be greater than the general population.[15] To keep data collection procedures comparable in cases and controls, we asked surrogates for the information for the controls. Disparaties in recall could still exist, but several features of our method minimized the influence that a live control could have had on a surrogate: the surrogate was not informed about the nature of the interview until the interviewer was present; controls were not allowed to be present during the interview; potentially sensitive questions (e.g., alcohol consumption) were asked toward the end of the interview.

Diseases such as pancreatic cancer which are rapidly fatal are difficult to study because many patients die before the interview can be completed or are too debilitated to participate. Previous case-control studies have suffered from this problem. Wives and daughters can provide reasonable estimates of a man's dietary habits, although the data on alcohol are less certain.[16–18]

The risk estimates and trends observed in this study are consistent with other results for cigarette smoking[2–11] and

*Adjusted for age, education level, reported diabetes mellitus history, cigarette smoking, alcohol and when appropriate meat and/or vegetable consumption. The frequency level was determined by the 25th and 75th percentile values of the controls in order to categorize low, moderate and high consumption patterns.

Beef = hamburger, pot roast, roast beef, steak, beef ribs.
Pork = pork chops, ham, ribs, roast, bacon.
Poultry = chicken, turkey.
Cruciferous vegetables = cabbage, broccoli, brussel sprouts, cauliflower.
Noncruciferous vegetables = spinach, carrots, lima beans, peas, tomatoes, corn, green and yellow beans.
Fruits and juices = oranges, apples, bananas, peaches, grapefruit, strawberries, orange juice.
Breads and cereals = white, whole wheat, rye bread, cereal.
Dairy = cheese, cottage cheese, ice cream, milk.

further support its role as an etiologic factor for pancreatic cancer.

Heavy alcohol consumption adjusted for several potential confounding variables was positively associated with pancreatic cancer. The consumption of beer and hard liquor contributed to this association, but there were few wine drinkers among the subjects. These results are supported by some[2–4] but not all epidemiologic studies on pancreatic cancer. This discrepancy, reviewed by Velema, *et al*,[19] may be due, in part, to differences in case selection, hospital versus population-based controls, the use of living or deceased controls when cases are deceased, and whether the vital status of the case affects the accuracy of information provided by a family member. Studies of alcohol abusers have not reported an excess risk for pancreatic cancer;[20,21] however, these studies did not allow for an adequate latency period and many abusers died of other causes.

Heavy alcohol consumption may induce chronic calcifying pancreatitis which may, perhaps in the presence of other dietary modifiers (e.g., high fat), lead to pancreatic cancer.[22] Animal models, however, have not shown pancreatic cancer to be produced by high concentrations of ethanol.[23] At this time there is no clear biologic mechanism to link alcohol consumption to pancreatic cancer.

It is probably premature to suggest, as some investigators have,[1,9] that alcohol does not have an important role in the development of pancreatic cancer. We agree with Velema, *et al*,[19] that the consumption of alcohol in relation to pancreatic cancer should remain under close observation.

Our findings concur with most epidemiologic[6–11] and laboratory[24] studies that coffee is not a risk factor for pancreatic cancer. In fact, after adjusting for major dietary life-style factors as recommended by Falk, *et al*,[10] we observed a negative association for coffee usage even at seven or more cups per day.

Ecologic studies have examined national food consumption patterns and pancreatic cancer mortality rates and have shown a positive correlation between pancreatic cancer and meat and fat consumption;[25,26] of four recent case-control studies, three have reported positive associations with meat. Mack, *et al*, observed a high level of beef consumption among directly interviewed subjects.[9] Falk, *et al*, showed a dose response for pork products.[10] Norell, *et al*, reported a positive association with meat that was fried or grilled.[8] However, Gold, *et al*, in their case-control study, did not find a relation with beef, deep-fried foods, smoked or barbequed

beef, bologna, or salami.[7] Laboratory data have suggested high fat diets may cause pancreatic hyperplasia which may subsequently lead to neoplasia.[27] Our findings support the hypothesis that diets high in animal fat may be associated with pancreatic cancer.

Our results showed a decreased risk of pancreatic cancer with an increased consumption of cruciferous vegetables. Indoles and aromatic isothiocyanates, found in cruciferous vegetables, have been shown to increase glutathione S-transference activity and inhibit experimentally induced neoplasia in laboratory animals.[28] The lack of a decreasing risk trend for consumption of noncruciferous vegetables was due to cases consuming more of the common vegetables (peas, corn, green bean and yellow beans). Unlike Norell, *et al*,[8] we did not observe a negative trend with carrots.

The risk estimates for fruit consumption showed at best a weak negative association. Others have reported much stronger negative associations.[7–10]

The increased risk for white bread has also been observed elsewhere.[7,9] This association may be due to a change from white to whole wheat bread by controls which may parallel their preference for a diet of more vegetables, less meat.

Based on the results of our study and those from previously published studies, we believe a cessation of cigarette smoking will result in a decreased incidence of pancreatic cancer in the adult male population. Furthermore, a decrease in heavy alcohol and meat consumption and a corresponding increase in vegetables may also contribute to a decline. Our results lend additional support to the conclusion that coffee is not a risk factor for pancreatic cancer.

Call for Abstracts

APHA Late-Breaker Epidemiology Exchange Session

The Epidemiology Section will again sponsor a Late-Breaker Epidemiologic Exchange at APHA's annual meeting in Chicago, Illinois. The Exchange, to be held on Wednesday, October 25, 1989, will provide a forum for presentation of epidemiologic investigations, studies, methods, etc , which have been conceived, conducted, and/or concluded so recently that abstracts could not meet the deadline for submission to other Epidemiology Sessions. Papers submitted should report on work conducted during the last 6–12 months.

Abstracts should be limited to 200 words; no special form is required. Abstracts should be submitted to Robert A. Gunn, MD, Division of Field Services, Epidemiology Program Office, Bldg. 1, Room 5127, C08, Centers for Disease Control, Atlanta, GA 30333—telephone; (404) 639-3187—and must be received by *September 15, 1989*.

The Reliability of Self-Reported Cigarette Consumption in the United States

Evridiki J. Hatziandreu, MD, DrPH, John P. Pierce, PhD, Michael C. Fiore, MD, MPH, Verner Grise, PhD, Thomas E. Novotny, MD, and Ronald M. Davis, MD

Abstract: To investigate the possibility that self-reported smoking is not a valid measure for assessing trends in smoking prevalence, we compared total self-reported cigarette consumption with the adjusted consumption data from cigarette excise taxes as reported by the US Department of Agriculture (USDA) for the period 1974 through 1985. Self-reported consumption was calculated by using data from the National Health Interview Surveys (NHIS) for adults and from the National Household Surveys on Drug Abuse for adolescents. For this period, the average ratio of self-reported cigarette consumption to the USDA estimate of consumption was 0.72 (range = 0.69 to 0.78). There was no statistical difference in this consumption ratio from year to year, indicating no apparent increase in the underreporting of cigarette smoking in these surveys. We conclude that cross-sectional surveys of self-reported smoking status remain a reliable surveillance tool for monitoring changes in population smoking behavior. (*Am J Public Health* 1989; 79:1020–1023.)

Introduction

Cigarette smoking has been identified as one of the major public health hazards of the 20th century. There are two standard approaches to measure the degree of exposure of the United States population to this hazard. The first approach uses information obtained in the process of collecting state and federal excise taxes and is an aggregate measure of population consumption. These data are regularly reported as total and per capita cigarette consumption by the Economic Research Service of the US Department of Agriculture (USDA). The advantage of the aggregate measure is that it is based on objective data that would not be affected by changing social attitudes towards smoking. The second approach is to survey a representative sample of the public and to ask questions regarding individual smoking behavior. This has been undertaken on a regular basis since the mid-1960s for the population of the United States by the National Center for Health Statistics and has been the basis of trend analyses of smoking reported elsewhere.[1–3] This latter measure, however, depends on the honesty and accuracy of respondents in reporting their own behavior.

The social acceptability of a behavior has been known to affect a person's willingness to admit engaging in that behavior[4] and may also affect the accuracy in reporting the number of cigarettes smoked per day. The social acceptability of smoking has decreased with decreasing smoking prevalence and increasing restrictions on smoking in public places.[5]

Using data from four national smoking surveys undertaken between 1964 and 1975, Warner concluded that the self-reported survey estimates of cigarette consumption increasingly underestimate consumption estimates from USDA during the period 1964 through 1975.[6] While he noted that this may have resulted from a change in survey methodology, he suggested that the finding was real and resulted from the increasing social stigma and personal health risk attached to smoking. If there has been increasing underreporting of smoking behavior, then the dramatic decrease in self-reported smoking prevalence reported elsewhere may be, in part, artifactual.[1,2]

Policy decisions with regard to smoking rely heavily on data from national surveys. It is essential therefore to document the validity and reliability of this method of measurement. In this report, we compared trends in the USDA estimates of cigarette consumption from 1974 to 1985 to estimates of consumption obtained from self-reported survey data collected during the same period by the National Center for Health Statistics and the National Institute on Drug Abuse. We also examined whether the trends in per capita consumption match the decline in smoking prevalence.

Methods

To calculate cigarette consumption, data from multiple sources were used. USDA publishes estimates of aggregate cigarette consumption. To estimate self-reported consumption, smoking behavior data from the National Health Interview Surveys and the National Household Surveys on Drug Abuse were analyzed. These data sources are described below.

USDA Estimate

The Economic Research Service of the US Department of Agriculture has made estimates of total and per capita consumption of cigarettes for a number of years. The estimates are based on data from the Bureau of Alcohol, Tobacco and Firearms of the US Department of Treasury, the Bureau of Commerce of the US Department of Commerce, the Tobacco Institute, and other private industry sources.[7]

The Tobacco Institute reports the number of packs of cigarettes on which state taxes are paid; the Bureau of Alcohol, Tobacco and Firearms reports the number of cigarettes on which federal taxes are paid; and the Bureau of Commerce reports the number of cigarettes imported into the United States. Both federal and state excise taxes are collected at the wholesale level (on removal from warehouses) and are not sales taxes. The tax-based data are then adjusted for estimated inventory changes and for returned unused products. Adult per capita consumption is calculated by dividing total consumption by the total US population 18 years of age and older for any given year.

Self-Reported Adult Consumption

The National Center for Health Statistics (NCHS), through the National Health Interview Survey (NHIS), has

This paper, submitted to the Journal October 18, 1988, was revised and accepted for publication February 7, 1989.

collected and made publicly available health information from a probability sample of the civilian, noninstitutionalized population of the United States since 1964. In cross-sectional surveys in 1974, 1976, 1978, 1979, 1980, and 1985, NCHS administered a supplemental questionnaire on tobacco use to a subsample of the population surveyed. These surveys included adults aged 18 years and older in 1983 and 1985, aged 19 years and older in 1976, and aged 17 years and older in 1974, 1978, 1979, and 1980. Detailed descriptions of the NHIS design and procedures have been published.[8,9] While the sample design of the NHIS changed in 1985, the changes were aimed at making the population estimates more precise. They do not invalidate comparisons among the estimates for the different survey years.

These supplemental surveys on tobacco use include self-respondents only (proxy responses were not allowed). When a selected respondent could not be interviewed in person, the survey was administered by telephone. The average response rate for the tobacco use supplements was 89.8 percent, with a range of 88.5 percent to 91.1 percent (NCHS unpublished data) and the sample size ranged from 9,553 in 1980 to 31,082 in 1985.[1]

The data were classified into age-sex-race groups and weighted to reflect the distribution of the US population for the survey year and the individual probability of selection as well as other survey design features. Ever smokers were defined as persons who reported that they had smoked at least 100 cigarettes in their lifetime. They were further identified as current smokers or former smokers based on responses to the question "Do you smoke now?" Respondents were asked how many cigarettes they smoked per day. We included in the analysis only survey data collected after 1974 because data collected prior to 1974 included proxy responses. Proxy reporting has been shown to underestimate the number of cigarettes smoked per day.[10]

Self-Reported Adolescent Consumption

Data on adolescents' smoking behavior are not available from the NCHS. However, the National Institute on Drug Abuse (NIDA) has conducted national household surveys of the civilian, noninstitutionalized population aged 12 years and older in the contiguous United States (Alaska and Hawaii excluded) in 1974, 1976, 1977, 1979, 1982 and 1985. These surveys use a self-administered questionnaire, administered in the household, and are based on a national probability sample of households. Respondents were asked the average number of cigarettes smoked during the past 30 days. The data are weighted to reflect selection probabilities based on age, sex, and race, and adjustments are made for nonresponses. The sample size in these surveys for those aged 12-17 years was approximately 2,000 for each survey year.

Analysis

Consumption Estimates—For each year, the total cigarette consumption is the amount smoked by: adult current smokers, adolescent current smokers, and former smokers who stopped smoking during that year. For each of these groups, the daily consumption is the product of the following three variables: 1) proportion of the group that is smoking (smoking prevalence); 2) the population size in each group; and 3) the average number of cigarettes smoked per day by each smoker in the group. Therefore, in each survey year, the consumption for each group equals the reported daily consumption times 365 days per year.

Calculations for adults were made using the public use data tapes available from NCHS for the years in which the supplements on smoking were conducted. Data for the adolescents were estimated from the NIDA surveys. We relied on published data for all years except 1985[11]; unpublished 1985 data were provided by NIDA (Joe Gfroerer, personal communication). Because the NIDA survey years differ from those of the NHIS, the prevalence and the average cigarette consumption were estimated by using linear intrapolation to match the NHIS years.

Census data were used to provide estimates of the appropriate age-specific population in the United States for each survey year.[12]

For current smokers covered by the NHIS, calculating the yearly consumption estimates was straightforward, using the smoking prevalence and the reported number of cigarettes smoked per day. Consumption by former smokers who quit in the year preceding the survey was estimated by using data from the combined 1978–1980 NHIS. For these three years, former smokers who quit during the previous year smoked an average of 192 days during that year, very close to half of the year. Accordingly, we assumed that former smokers who quit prior to the survey smoked for half of the year.

Because some adolescents also began to smoke during the year of the survey, self-reported cigarette consumption during the 30 days prior to the survey multiplied by 12 months overestimates adolescent yearly consumption. We had no valid and reliable national data to adjust for this overestimate. On the other hand, our data underestimate actual adolescent consumption because they do not include consumption by "experimental smokers" who had smoked during the year but had not done so in the 30 days prior to the survey. We conducted a sensitivity analysis to determine how assumptions made in calculating cigarette consumption affected the results of the analysis.

Consumption Ratios—Using both sources of cigarette consumption, we calculated a consumption ratio for each year by dividing the total self-reported cigarette consumption by the USDA estimate of consumption. This measure expresses the self-reported data as a fraction of the USDA estimate.

Statistical Analysis—Data were analyzed using STATISTIX,[13] an interactive program for microcomputers. A least squares line of best fit was calculated for both the per capita consumption and for the consumption ratios.

Results

The USDA estimate of cigarette consumption in the United States increased steadily from 1974 through 1981, when an estimated total of 640 billion cigarettes were smoked. Since 1981, this estimate of cigarette consumption has steadily declined despite increasing population size; in 1986, the number of cigarettes consumed was 584 billion (Table 1).

Per capita consumption decreased steadily from 4,141 cigarettes per year in 1974 to 3,274 in 1986 (Table 1). A regression line was fitted to these data and this line described the data well ($R^2 = 0.95$). The average reduction in per capita consumption was 75.4 cigarettes per year, (95% CI = 65.1, 85.7).

The USDA estimate of total cigarette consumption, self-reported cigarette consumption (based on NCHS and NIDA surveys), and the consumption ratios for the selected years from 1974 through 1985 are shown in Table 2. Although self-reported consumption is less than the USDA estimate of

TABLE 1—USDA Estimates of Total Cigarette Consumption and per Capita Consumption, United States, 1974 through 1986

Year	Estimated Total Cigarettes Consumed per Year (billions)	Estimated* per Capita Consumption of Cigarettes Per Year
1974	599.0	4,141
1975	607.2	4,123
1976	613.5	4,092
1977	617.0	4,051
1978	616.0	3,967
1979	621.5	3,861
1980	631.5	3,844
1981	640.0	3,836
1982	634.0	3,739
1983	600.0	3,488
1984	600.4	3,446
1985	594.0	3,370
1986	583.8	3,274

consumption at each year, this relationship appears to be constant over time. The consumption ratios ranged from 0.78 in 1983 to 0.69 in 1976, with a mean of 0.72. The slope of regression line is not significantly different from zero ($p = 0.85$), strongly suggesting the lack of any change over time in the consumption ratio. The components of the self-reported cigarette consumption data for each year and for each of the three groups are shown in Table 3. The contributions of adult former smokers and adolescent smokers are small relative to the amount smoked by adult current smokers.

Sensitivity Analysis

For the former-smoker and the adolescent components of total self-reported consumption, assumptions that were used in calculating self-reported consumption were:

- former smokers who quit during the preceding 12 months quit on average at the mid-point of the year; therefore, they were smoking for 182 days (rather than 192 days estimated from the 1978–80 surveys);
- adolescent data could be interpolated from the NIDA survey years to the NHIS years;
- the impact of adolescents who took up smoking during the preceding year and the impact of the experimental smokers who did not smoke in the 30 days prior to the survey were small and canceled each other out.

The results were not altered when 192 days was used instead of 182 days. The mean consumption ratio was

TABLE 2—USDA and Self-Reported Cigarette Consumption Estimates, United States, Selected Years 1974 through 1985

Year	USDA Estimate (billions)	Estimate from Self-Reported Data (billions)	Consumption Ratio
1974	599.0	434.86	0.726
1976	613.5	424.36	0.692
1978	616.0	438.38	0.712

affected at the third decimal place (0.720 versus 0.721). This lack of effect is partially due to the small contribution of former smokers to the total amount of the self-reported consumption. The contribution of the adolescent smoking component to total consumption was even smaller than that of former smokers for each survey year (Table 3). It ranges from 2.2 percent to 4.5 percent of the total self-reported consumption. If it would increase by 50 percent at each year, the mean consumption ratio would be affected at the second decimal place (0.720 vs 0.732); therefore variations in this component are not likely to influence the results substantially either. Given this small impact of adolescent smoking, an overlap between the two surveys for the lower age bound (those aged 17)—which occurred in the years 1974, 1978, 1979, and 1980—is not likely to have a major effect. Overall, over 90 percent of the total self-reported consumption is attributed to current smokers for whom relevant data are readily available.

Discussion

Measurement of any quantity raises issues of validity and reliability. The findings of this analysis, comparing USDA estimates of cigarette consumption to self-reported smoking consumption, 1974 through 1985, address both questions. The consumption ratio 0.72 represents a considerable discrepancy between the two measures. It is unlikely that this discrepancy between the USDA and the self-report estimates stems from the former and adolescent components of the total consumption because they account for less than 10 percent of the total consumption. It may be that adult current smokers do not report their smoking status correctly, but the literature does not support this conclusion. Findings from biochemical validation studies[14,15] suggest that self-reported cigarette consumption prevalence is a valid estimate of smoking status in the population. An alternative explanation may be that current smokers consistently underreport the number of cigarettes they smoke. This underreporting may occur disproportionately among those who are heavier smokers, analogous to the underreporting of alcohol intake.[16]

Alternatively, it might be from a systematic rounding down of the number of cigarettes smoked per day as respondents have a preference to report daily consumption in multiples of a half-pack of cigarettes and therefore report the closest half-pack consumption below their actual consumption level.[5,17]

The ratio between the two estimates is constant over time, strongly suggesting that self-reported data from these national surveys are reliable, despite any increasing social unacceptability of smoking which could theoretically bias the accuracy of self-reported data. A bias could occur if the two components of the self-reported consumption estimate, i.e., prevalence and daily consumption, change differentially over time. Prevalence has been decreasing steadily since 1974.[1,2] Daily consumption, however, remained relatively constant over time.[5]

These findings differ from the conclusions drawn from the study by Warner[6] who reported that the consumption ratio decreased from 0.73 in 1964 to 0.64 in 1975. This earlier analysis used data from the 1964, 1966, 1970, and 1975 Adult Use of Tobacco Surveys. These surveys, however, used different methodologies, particularly with respect to the mode of data collection. The 1964 and 1966 surveys used in-person interviews, whereas the 1970 and 1975 surveys used telephone. The consumption ratios obtained for 1964 and 1966 (0.73 and 0.72, respectively), using in-person survey data, are similar to the mean ratio of 0.72 observed in our study from in-person surveys during the period 1974 to 1985. Therefore, there is no evidence for an increase in underreporting when comparing in-person survey data from the 1960s with data from 1974 to 1985. The drop in consumption ratio reported by Warner between 1966 and 1970 is probably best explained by the change in the interview mode, because telephone surveys generally provide slightly lower estimates than in-person household surveys.[5]

One might ask whether it is more appropriate to use the USDA estimates of cigarette consumption, which are more objective and easily available, or self-reported data such as the NCHS or the NIDA surveys, as the primary source for surveillance of smoking in the population. The USDA estimate is a single overall figure. However, such a figure does not provide the number and types of people who smoke or the number of cigarettes each smoker consumes and hence cannot be used to target antismoking programs. On the other hand, trend analyses of self-reported smoking[1–3] do provide the smoking behavior of individuals in the population (and in sociodemographic subgroups) both in terms of smoking status and daily consumption patterns. The aggregate estimate may be more sensitive to influences of anti-smoking activity than estimates of smoking prevalence because, for many people, it may be easier to reduce the number of cigarettes smoked per day than to quit smoking. This aggregate estimate, however, cannot distinguish between a large number of people reducing the amount they smoke and a smaller number who actually quit.

The most important public health goal is to reduce smoking prevalence, not simply to reduce the number of cigarettes consumed by each smoker. Even though a reduction in daily cigarette consumption has some health benefits, these are smaller than those of quitting smoking.[5,18] Our results support the use of self-reported cigarette smoking from national surveys as a reliable surveillance tool, essential in monitoring progress toward achieving the 1990 health Objectives for the Nation,[19] and a smoke-free society by the year 2000.

Two Episodes of Acute Illness in a Machine Shop

THOMAS SINKS, PHD, PETER R. KERNDT, MD, AND KENNETH M. WALLINGFORD, CIH

Abstract: Following an explosion in a machine shop and temporary plant closure, on the day the plant returned to full operations a degreaser malfunctioned. Workers in the assembly room were exposed to trichloroethylene levels later estimated to have exceeded 220 ppm (OSHA PEL 100 ppm). The plant was evacuated and the degreaser taken out of operation. Blood testing for carbon monoxide (CO) on five employees found carboxyhemoglobin levels in excess of normal. The plant reopened the following morning. Over the next two weeks, 15 employees were seen by the plant nurses for similar complaints; although all returned to work, their carboxyhemoglobin levels, later found to be inaccurate, were reported by a local medical clinic to range from 13.7 to 20.0 percent. At the end of the second week, another outbreak of illness occurred, but carboxyhemoglobin, trichloroethylene, fluorocarbons, and methylene chloride were not elevated in all 17 persons tested; plant-wide monitoring for CO found no elevated levels. During the first outbreak of illness, cases were 2.26 times as likely to have entered the assembly room as noncases. During the second outbreak, cases were no more likely than noncases to have entered the assembly room. We believe the explosion, earlier toxic exposures and illness, and the misleading blood test results led to plant-wide anxiety which culminated in a collective stress reaction and the second outbreak. An open meeting with all employees, informing them of our findings, provided reassurance and no further episodes of illness occurred in this workforce. (*Am J Public Health* 1989; 79:1024–1028.)

Introduction

Disease is the result of the interaction between a host, an agent, and the environment. The host must be susceptible to the agent and the environment dictates if the agent and host contact each other. In this paper, we describe two outbreaks of illness in a manufacturing plant within 16 days. Whereas the workers' symptoms were similar on both days, the agents and environments differed. Although the outbreaks were not independent of one another, we believe they represented separate illnesses with unique causes.[1]

The 225,000 sq ft factory manufactures rotary compressors for small air conditioners. At the facility, internal compressor parts are machined to specifications using a variety of machine tools. Welding, brazing, painting, and soldering operations are used as appropriate during compressor assembly. The majority of the workers are unskilled and assigned to the same daily task with little or no variation in their day-to-day routine. A floor plan of the plant is presented in Figure 1.

Chronology of Events

A time line and chronology of events is presented in Figure 2.

On January 29, 1986, a regulator valve on the fuel line to the plant boiler malfunctioned resulting in a large explosion. Fortunately, this occurred while second shift workers were on break in a second floor lunchroom. No one was injured.

The plant reopened on February 3. First shift began at 7:30 am. Between 8:35 am and 12:30 pm, 10 employees became acutely ill and were taken to the local emergency room where they were evaluated at a local hospital for a presumed toxic inhalation. Their symptoms included headache, dizziness, disorientation, eye and throat irritation, nausea, vomiting, shortness of breath, and chest pain. Arterial blood samples, drawn for carboxyhemoglobin determination, were elevated in five workers (mean 14.0 percent, range 13.3–14.8 percent). All workers were treated and released. By early afternoon, first shift production was stopped; second shift workers were sent home as they reported for work.

State OSHA (Occupational Safety and Health Administration) inspectors and an industrial hygiene consultant hired by the company arrived that afternoon. Direct-reading mea-

Dr. Kerndt is with the County of Los Angeles Department of Health Services, California; Mr. Wallingford is with Datachem Inc, Cincinnati, OH. This paper, submitted to the Journal October 27, 1988, was revised and accepted for publication February 2, 1989.

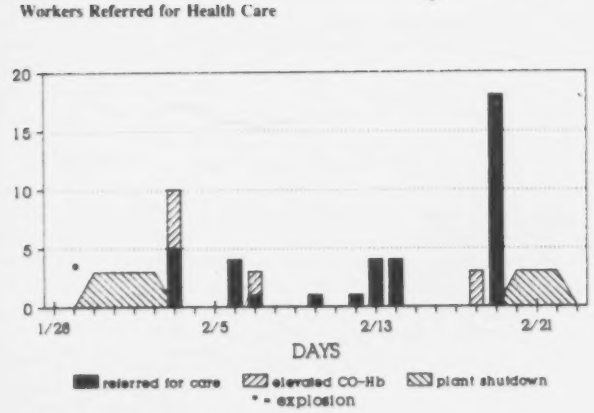

FIGURE 2—Time Line and Sequence of Events from Explosion January 28 through February 21

surements for carbonmonoxide (CO) were made throughout the plant but none exceeded the federal OSHA standard, the ACGIH threshold limit value (TLV), or the NIOSH (National Institute for Occupational Safety and Health) recommended standard.[2–5] Propane forklifts, open flames in the welding and brazing operations (located within the assembly room), and a portable heater were identified as CO sources. Two of seven forklifts, emitting excessive CO, were taken out of service, pending repair.

Workers interviewed the same day reported that the degreaser, started two hours before the beginning of first shift, had emitted trichloroethylene fumes into the assembly room. Following the explosion, the degreaser had been surrounded by polyurethane curtains to prevent contamination of compressor parts with residue from the explosion (Figure 1B). The curtains had enclosed not only the degreaser but also two openings in the assembly room wall through which parts were normally conveyed to and from the degreaser. On the morning of February 3, the degreaser malfunctioned. Apparently, the trichloroethylene level had fallen below the operating range and then overheated; excess fumes trapped within the polyurethane curtains escaped into the assembly room.

The degreaser was removed from operation but was restarted two days later to simulate the conditions of February 3. Measurements taken two hours after start up found trichloroethylene concentrations of 224 parts per million (ppm) in the assembly room. The OSHA permissible exposure limit (PEL) for trichloroethylene is 100 ppm as an 8-hour time-weighted average (TWA) and 200 ppm as a ceiling concentration.

Full production resumed the next day. Between February 4 and 18, 15 employees were seen in the plant infirmary with complaints of headache, eye and throat irritation, nausea, fatigue, and muscle aches. Twelve employees sought treatment at local medical facilities because of concern about continuing exposures at work. One clinic drew venous blood samples for carboxyhemoglobin determination from five workers. All were elevated, ranging from 13.7 to 20 percent. Three workers were told of their elevated carboxyhemoglobin levels while at work, during the morning of February 19. Local newspaper accounts of the February 3 mishap were published daily over the next four days. On February 13, the press had reported that another employee had been rushed to the hospital, "overcome by toxic fumes." All environmental samples for CO were well below the NIOSH recommended exposure level (REL) of 35 ppm.

On February 19, between 9 am and 11 am, workers again became acutely ill. Most were triaged from the single room plant infirmary where they could be found sitting or lying on either the floor, examining table, or stretchers. Two workers lost consciousness for a brief period. Fifteen workers were transferred by ambulance to the hospital. Emergency medical technicians carried stretchers through the plant production area as they left the facility. Four additional workers later requested a medical evaluation. Production at the plant was stopped.

At the hospital, 17 employees were tested for elevated carboxyhemoglobin levels, all tested normal (mean 2.3 percent, range 0.0–8.0 percent). Additional toxicologic screening for trichloroethylene, fluorocarbons, and methylene chloride was also negative.

State OSHA investigators inside the plant during the outbreak found CO levels less than 15 ppm.

NIOSH Investigation

NIOSH investigators arrived the next day. Our evaluation included an environmental survey and a review of the medical findings. With the exception of the trichloroethylene exposures on February 3, no environmental sources of toxic exposures likely to have caused acute illness were identified.

A review of medical records showed that treatment had consisted of monitoring vital signs, administering oxygen, and an occasional precautionary intervenous line. Although CO levels inside the plant were low, all carboxyhemoglobin levels in employees seen at the clinic from February 4–18 were elevated. At the same time, no carboxyhemoglobin levels were elevated at the hospital after February 3. One of us (PRK) submitted samples of his blood for carboxyhemoglobin determination on February 20. Results from the hospital were 0.03 percent, while the clinic results were 16.0 percent. Two additional samples, collected at the clinic from employees on February 21 (two days after the plant was closed) were also elevated, with carboxyhemoglobin levels of 16 percent and 20 percent. The inaccuracy of the clinic carboxyhemoglobin values were later confirmed by the regional laboratory director.

During meetings with the union and management, the decision was made to re-open the plant. An open meeting was held for all employees on February 23 informing them of our findings. NIOSH investigators reassured workers that the plant environment was safe and would continue to be monitored. Plant operation began immediately following the morning meeting.

Questionnaire

On February 25, a questionnaire was administered to 325 employees (279 first shift and 46 second shift workers). Second shift workers and eight others who had not worked on February 3 and February 19 or did not adequately complete the questionnaire were excluded. Employees ranged in age from 18 to 62 years with a mean of 33 years; 67 percent were

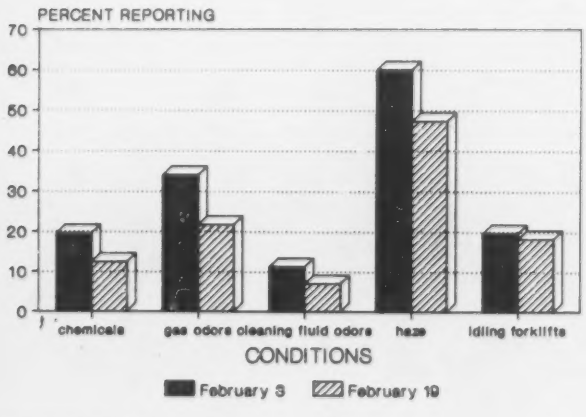
male. Almost 30 percent of the employees had not finished high school, 42 percent were high school graduates, 21 percent had some college or vocational training, and 7 percent were college graduates.

Figure 3 illustrates the proportion of employees who reported the presence of certain conditions in the plant. The presence of chemicals, odors of gasoline and cleaning fluid, and visible haze was reported by a greater percentage of workers on February 3 than on February 19.

Headache was the most common symptom on both February 3 and 19, with greater than 20 percent of the workforce reporting it. Other reported symptoms included sleepiness, sore throat, lightheadedness, nausea, and weakness. The percentage of employees reporting each symptom was similar on the two days. In order to define a case, we used the occurrence of headache plus a varied number of additional symptoms. If the number of symptoms experienced by an individual had been a function of exposure, we would expect that workers with an increased number of symptoms had received an increased exposure. This would result in a case definition that became more specific for exposure as it became more restrictive.

Employees were asked to recall their time spent in the assembly room on February 3 and February 19. Eighty-seven of 240 and 79 of 245 employees entered the assembly room on February 3 and February 19, respectively. On February 3, entry into the assembly room was associated with illness; the relative risk ranged from 1.33 to 3.10, increasing as the case definition became more restrictive (Table 1). No association between illness and entry into the assembly room was observed on February 19. Time spent in the assembly room was also associated with illness on February 3, but not on February 19 (Table 2).

On both days, women were more likely than men to become ill. On February 19, women throughout the plant had a two-fold increased risk of illness (RR = 1.99, 95% CI = 0.93, 4.23). In contrast, on February 3, women entering the assembly room were at greatest risk (RR = 3.15, 95% CI = 1.06, 9.37) while the RR for women versus men who did not enter the assembly room on February 3 was much lower (RR = 1.24, 95% CI = 0.35, 4.43).



Reported by 1st shift workers

FIGURE 3—Workers' Perceptions of Conditions Inside a Machine Shop during Two Episodes of Acute Illness.

Discussion

Our findings suggest that the cause of illness on February 3 differed from that on February 19. The illness of February 3 appears to have been the result of the toxic effects of CO complicated by exposure to trichloroethylene. The illness of February 19, however, more likely represents a collective stress reaction. The combination of the boiler explosion on January 29, toxic exposures on February 3, reports in the local press, and the misleading laboratory results reported to employees on February 19 led to plant-wide anxiety, which precipitated the acute outbreak of illness on February 19.

On February 3, presence in the assembly room was associated with illness and this association was strengthened by both an increase in the number of symptoms and time spent in the assembly room. Unfortunately, the cause of the elevated carboxyhemoglobin levels of February 3 was not identified. Contact with strong alkalies may cause trichloroethylene to decompose into CO, phosgene, and dichloroethylene.[6] However, no strong alkalies were found in the assembly room and symptoms suggestive of phosgene poisoning were not reported.

The February 19 outbreak shares a number of common features with other reports of collective stress reaction.[7–12] No exposures were identified in the work environment at the time of the illness. The ill workers developed a wide variety of relatively severe symptoms, which contrasted sharply with a lack of physical findings. The spread of illness was very rapid, resembling an acute chemical poisoning rather than an outbreak of infectious disease. Perhaps most important, a very high level of stress had been building in this workforce since the boiler explosion on January 29.

In the workplace, collective stress reaction has been reported most often among groups of unskilled workers with less than a high school education performing highly repetitive unskilled tasks.[11] In those reports, women were more likely to have been affected than men. It should be emphasized that the association of gender and educational level with collective anxiety phenomenon does not imply that these are causative factors. The nature of the job, rather than gender or education, may place these workers at high risk.

Whenever workers are exposed to toxic substances, both they and their unexposed co-workers are subjected to psychological stress and the situation may produce collective stress reactions above and beyond the primary symptoms. This, in turn, can precipitate additional illness episodes, such as the one illustrated in this paper. This emphasizes the importance of a thorough and sensitive debriefing of the workers following any environmental or medical assessment. If worker fears and suspicions are not sufficiently allayed and episodes of illness do recur, both the investigators and the management can lose credibility, and the situation may escalate.

The conclusion that an outbreak is the result of collective stress reaction should be made with caution. There is always the chance that an undetected toxic exposure has been overlooked.[13–15] Illness resulting from psychologic factors is "real" in every respect. The term refers to illness in which the primary cause is psychological stress, arising from the occupational and/or general social environment, rather than environmental chemical, physical, or infectious agents. The occurrence of a collective stress reaction does not imply a psychiatric disorder. It represents a normal psychophysiological response to a stressful environment.

TABLE 1—Percentage of Ill Workers by Exposure in the Assembly Room, Risk Ratios, and p-values

	Headache + 1 Symptom	Headache + 2 Symptoms	Headache + 3 Symptoms	Headache + 4 Symptoms	Headache + 5 Symptoms
February 3					
% Assembly Room employees ill (N = 87)	17.2	16.2	13.1	13.1	12.1
% Other employees ill (N = 153)	13.0	9.7	5.8	5.2	3.9

The 1990 Census: Size and Scope

The 1990 Census of the United States will be the 21st in the nation's history and the largest and most complex ever undertaken. The Census Bureau has been planning the mammoth operation since 1984. The size and scope of the 1990 Census will include:

- *Expected count*—250 million people, 106 million housing units.
- *Employment*—Will hire about 565,000 people, with 300,000 working at peak.
- *Location:* 484 field offices, 13 Regional Census Center, 7 processing offices.
- *Coverage*—Over 106 million questionnaire packages to print, label, and process.
- *Geography*—Computerizing entire map base, including over 250,000 different base maps. Nearly 7 million maps will be generated to help census takers collect questionnaires.
- *Participation*—Over 70 million mail returns within two weeks of Census Day, April 1, 1990.
- *Technology*—Using 570 minicomputers in field offices, to be set up, used, and dismantled in one year.
- *Mandated Completion*—Deliver apportionment counts to the President by December 31, 1990; provide data necessary for redistricting to states no later than April 1, 1991.

Most households will receive a mailed questionnaire about a week before Census Day. Others, depending on location, will have forms delivered by census takers. Roughly five out of six households will receive a short form; one in six will be asked to fill out a longer form.

The questions are basic. The *short form* asks about race, Hispanic origin, age, marital status, rent or own residence, number of rooms, etc. The *longer form* asked additional questions on ancestry, employment, education, income, type of housing, utilities, etc.

The population count for various areas of the nation is put to numerous uses, e.g., to determine how many seats a state will have in the US House of Representatives; to allocate seats in state legislatures, and to benefit specific populations and programs. Billions of dollars of federal funds are returned to states, local governments, and to American Indian reservations and Alaska Native villages. State funds are returned to cities and counties, with amounts based in part on population or housing data. Planners use census facts to determine where to locate hospitals, schools, day care and senior citizen centers. Various special programs receive funds based on census information. Businesses use the data for decision-making involving expansion and jobs.

For a number of reasons, about 2.2 million people were not counted in the last US Census (about 1 percent). Among minority populations, the undercount was higher—about 6 percent. To help assure a complete count in the 1990 Census, the Bureau of the Census began distributing information in June to US local and tribal government officials. Known as the Local Review Program, the effort encourages officials in the nation's 39,000 local and tribal governments to voluntarily check Census Bureau maps and block-by-block housing unit counts compiled from a master list created and updated throughout the census period. Coupled with that mailout, approximately 470 half-day local review training sessions will be held throughout the US before the end of 1989.

Lead Absorption in Indoor Firing Range Users

SARAH E. VALWAY, DMD, MPH, JOHN W. MARTYNY, CIH, PHD, JEFFREY R. MILLER, CIH, MAGDALENA COOK, MS, AND ELLEN J. MANGIONE, MD, MPH

Abstract: To determine if users of indoor firing ranges may be at risk from lead exposure, we studied a law enforcement trainee class during three months of firearms instruction. Blood lead levels were obtained before training and at four-week intervals during training. Air lead levels were measured three times during instruction. Blood lead levels rose from a pre-training mean of 0.31 μmol/L to 2.47 μmol/L. Mean air lead levels were above 2,000 μg/m^3, more than 40 times the Occupational Safety and Health Administration's standard of 50 μg/m^3. Cumulative exposure to lead and the change in blood lead were positively correlated. Control measures need to be studied to determine their efficacy in decreasing or eliminating this health risk. (*Am J Public Health* 1989; 79:1029–1032.)

Introduction

Indoor firing ranges have been the subject of several studies of occupational lead toxicity. These investigations have documented elevated blood lead levels and associated adverse health effects in employees and instructors at these ranges.[1–5]

Lead exposure in indoor firing ranges occurs primarily through inhalation of lead particulates suspended in the range air. The major sources of airborne lead in the breathing area of the shooter result from the ignition of primer material containing lead styphnate (a highly explosive compound used to initiate the combustion of gunpowder in the cartridge) and, because the gun barrel and the bullet do not always align exactly, the shearing of lead particulates off of the bullet as it passes through the weapon. Fragmentation of bullets when they strike the target or backstop may also contribute to the overall air lead concentration in the firing range.[1,6–8]

In 1985, the Colorado Department of Health began an Occupational and Environmental Disease Surveillance Program monitoring exposure to heavy metals as well as other environmental exposures and work-related outcomes. Through this program, laboratories were requested to report elevated values for lead, cadmium, arsenic, and mercury. (Since October 1988, elevated blood or urine levels for lead, cadmium, arsenic, and mercury have been required to be reported to the Colorado Department of Health.) During 1985 and 1986, 11 reports of elevated blood lead levels were received; about half from employees of indoor firing ranges and the rest from frequent users of indoor firing ranges. These persons had blood lead levels determined for various reasons; awareness that use of an indoor firing range may be a health hazard, physician impression of lead toxicity, and requirement for an employment physical. While occupational studies have suggested that exposure to lead from indoor firing ranges may be a health risk for frequent users of these ranges,[2,6,9] the extent of risk among users has not been documented. This concern prompted us to conduct a study to determine the amount of lead absorbed into the body by regular users of an indoor firing range.

She is with the Division of Field Services, Epidemiology Program, Centers for Disease Control, assigned to the Colorado Department of Health at the time of the study. Dr. Martyny is with the Tri-County Health Department, Englewood, CO; co-authors Miller, Cook, Mangione are with the Colorado Department of Health, Division of Disease Control and Environmental Epidemiology, Denver. This paper, submitted to the Journal September 26, 1988, was revised and accepted for publication February 16, 1989.

Methods

Seventeen members of a beginning law enforcement trainee class were enrolled in this study on January 29, 1987, before the start of any firearm training or practice on the range. After informed consent was obtained, questionnaires to obtain demographic information and to determine any other potential sources of lead exposure were completed and blood was drawn to obtain baseline values for blood lead and free erythrocyte protoporphyrin (FEP) levels. A second questionnaire was administered on May 3, 1987, after firearms training was complete, to assess any self-reported symptoms of lead toxicity and to again ascertain any other potential sources of lead exposure which may have occurred during the training period.

The class began firearms instruction on February 3, 1987, and ended on April 28, 1987. A log was kept by the trainees indicating the booth each person occupied and the time spent on the range for each day of training. Smith and Wesson* stainless steel K frame Model 66 .357 caliber revolvers and .38 special caliber + P, reloaded, lead semi-wad cutter cartridges, manufactured by 3D INV* were used throughout the firearms training.

Blood was drawn at approximately four-week intervals (January 29, March 3, March 31, and May 3) to determine blood lead and FEP levels. After training was complete, the class dispersed throughout the state; only nine of the 17 trainees were available for blood sampling six weeks after completion of training. No physical examinations or other medical tests were done. Laboratory analyses were performed by ESA Laboratories in Bedford Massachusetts, using anodic stripping voltammetry without digestion for blood lead levels and the Chisolm Brown extraction method for FEP levels.[10–13] Since 0.24 μmol/L was the lower level of detection for blood lead, results that were <0.24 μmol/L on January 29 were set at 0.12 μmol/L for statistical analyses.

Air samples were taken from each occupied booth on the firing range on February 3, March 3, and March 31. Air sampling was also done in the classroom directly across the hall from the firing range and in the control room to determine exposure levels while in either room. Battery powered SKC model 224-37 universal flow personal air sampling pumps coupled with 37-mm mixed cellulose ester filters and closed cassettes were used for air sampling. The pump flow rate was set at approximately 2 liters per minute. Sampling pumps were calibrated before and after every sampling period using

*Throughout this paper, any mention of commercial names or products is for identification purposes only and does not constitute endorsement by the authors or the agencies for which they work.

a 2-liter bubble buret. Filters were analyzed by the Colorado Department of Health Laboratory using atomic absorption spectrophotometry. Field blanks were submitted with each set of samples for quality control. Pumps in the classroom and the control booth were placed on counter tops. The pumps on the range were attached to the overhead structure about six inches above the trainee's head. They were turned on when the trainees entered the range and turned off after their shooting session was completed.

During this study, two changes were made to the ventilation system of the firing range. The first, on February 5, corrected the positive pressure inside the range that had allowed lead-contaminated air to flow from the range into other parts of the building whenever the range door was opened. On March 9, final adjustments consisted of placing fins on the air supply grill to cause smoother air flow across the firing line and to decrease air turbulence. Air lead levels were determined before and after adjustments to the ventilation system. The air lead levels on February 3 were used as exposures for February 3 and 4 only. Air lead levels measured on March 3, were used as estimates of exposure levels from February 5 through the day before final adjustments were made. Results from the third air sample on March 31 were used as exposure levels after changes to the ventilation system were complete. In addition to the regular training, the March 31 session also included a very short (3 to 12 minutes) session of "dual-image" shooting with only one recruit on the range at a time. The air lead concentration determined for this session was used as the approximate exposure for the five times "dual-image" shooting was conducted.

Data were categorized into time periods based on the dates of blood sampling and firearms training: *Period 1*, January 29–March 2; *Period 2*, March 3–March 30; and *Period 3*, March 31–May 3. Each person's approximate exposure to airborne lead was established for each time period based on time spent on the firing range, the booth each person occupied, and air lead concentrations for each booth as determined from the three air samplings. For Period 1, we examined the change in the blood lead levels by the cumulative exposure to airborne lead. Cumulative exposure was obtained by multiplying the air lead concentration at each booth by the time spent on the range for each trainee each day of training and adding the totals for the six training days during this time period.

To assess the effect of using jacketed ammunition on the air lead concentrations, a final air sampling was done on April 30 using three different types of ammunition. Each test period consisted of the firearm instructors firing 60 rounds in approximately 10 minutes. In the first sampling period, copper-jacketed bullets were used; in the second, nylon-clad bullets; and in the third, the lead bullets that were normally used.

Results

Fifteen of the 17 trainees (ages 24 to 40, mean 30.7) were males. Only one person had a history of potential occupational exposure to lead during the previous year. His blood lead level upon entry into the study was the highest of the group, at 1.11 μmol/L. Baseline blood lead levels for the others were at or below 0.53 μmol/L, with a mean for these 16 of 0.26 μg/dl and a mean for all 17 of 0.31 μmol/L (Table 1).

TABLE 1—Blood Lead Levels of Law Enforcement Trainees, μmol/L, Colorado, 1987

Trainee	Date Sample Was Taken				
	1/29/87	3/03/87	3/31/87	5/03/87	(6/10–6/18)

8	0.29	3.19	2.61	2.46	1.74
9	<0.24	1.50	1.69	1.79	
10	1.11	1.93	2.04	2.32	
11	0.29	2.79	1.93	2.03	
12	<0.24	2.03	1.59	1.25	
13	0.29	no data	no data	1.59	1.16
14	<0.24	3.52	2.65	2.22	1.45
15	0.29	1.98	1.88	1.79	0.97
16	0.24	2.37	2.12	2.12	
17	0.29	2.75	2.99	2.32	1.45
Mean	0.31	2.47	2.14	1.91	1.20
Median	0.29	2.49	2.08	1.93	1.16

Mean change 1/29–3/03 = 2.16 μmol/L
Mean change 3/03–3/31 = −0.34 μmol/L
Mean change 3/31–5/03 = −0.23 μmol/L

During firearms training, the class was on the range a total of 17 days: six days in *Period 1*; five in *Period 2*; and six in *Period 3*. The time spent on the range each day varied, depending upon the type of training being done. In addition, the number of rounds fired by each trainee each day also varied, but was approximately 120 rounds per hour of training (Table 2).

At the end of Period 1, after just seven hours of shooting over that four-week period, the blood lead levels were elevated, from a pre-training mean of 0.31 μmol/L to 2.47 μmol/L (Table 1). Thereafter the levels decreased slightly. The blood lead levels for all nine trainees who had a fifth blood sample drawn decreased between the fourth and fifth sample, from a mean of 1.90 μmol/L to 1.20 μmol/L.

The FEP levels rose throughout the entire study period from a pre-training mean of 0.49 μmol/L to 1.27 μmol/L at the end of the study (Table 3). The FEP levels for the nine trainees who had blood drawn about six weeks after completion of training all showed a decrease from the May 3 level, dropping from a mean of 1.53 μmol/L to 1.23 μmol/L.

Air lead concentrations for each occupied booth are

TABLE 2—Amount of Time the Law Enforcement Trainees Spent in the Firing Range and the Approximate Number of Rounds Fired, per Time Period

Time Period	Number of Days	Mean Total Time (hours)	Range	Mean Time per Session (minutes)	Range	Rounds Fired

Mean change 1/29–5/03 = 0.79 μmol/L

shown in Table 4. Final adjustments to the ventilation system completed on March 9 probably contributed to the large decrease in the amount of airborne lead to which each person was exposed, as evidenced when comparing concentrations from the March 3 sampling with those from March 31 sampling. The data also show that the different booths on the range had very different air lead concentrations, both before and after changes were made to the ventilation system. The air lead concentrations in the classroom and control room dropped to below detectable levels after the first adjustment in the ventilation system.

The cumulative exposure to lead was directly related to the change in blood lead in Period 1 (Figure 1). We estimated lead exposure for the subjects not included in this figure by averaging the concentrations for the booths on either side of

***Includes only the 10 trainees with complete data.**

the one with a failed pump, and redid this analysis; the results were very similar.**

Symptoms possibly related to lead exposure were reported by three trainees who complained of having a metallic taste in their mouth throughout most of the training.

The results of the air sampling using alternative ammunition (Table 5) indicated that substantial reductions in airborne lead were obtained through the use of the jacketed bullets. A 97 percent reduction occurred when using the copper-jacketed bullets.

Discussion

All of the blood lead levels collected on March 3, after four weeks of training, were above 1.45 μmol/L, considered elevated for non-occupational exposures; 14 were >1.93 μmol/L, the value at which the Occupational Safety and Health Administration (OSHA) requires active medical surveillance in occupational settings; and four were >2.90 μmol/L, the level at which OSHA requires medical removal from the source of exposure.[14] Even though most of the blood lead levels began to drop after March 3, only two trainees had a blood lead level below 1.45 μmol/L by the end of the study, and eight still had levels >1.93μmol/L.

The decrease in the blood lead levels after March 3 could be attributed to the lower mean time spent on the firing range and amount of ammunition fired by each recruit during March and April, final adjustments to the ventilation system, and five days of "dual-image" training where only one trainee at a time was on the range for a very short period of time and exposed to much lower levels of lead (205 μg/m³ versus an average of over 2,000 μg/m³—Table 4).

**Data available on request to authors.

TABLE 5—Air Lead Levels in μg/m³ Using Different Types of Ammunition, 8-hour Time-Weighted Averages, Colorado, 1987

9	1345.8	100.5	70.2
Mean	1410	78.3	43.1
Reduction	—	94.5%	97.0%

While the blood lead levels began to decrease after March 3, the FEP levels continued to increase. At the end of the study, 11 trainees had FEP levels >0.89 μmol/L, a level at which lead poisoning would be considered a more likely cause than iron deficiency anemia, which may also elevate the FEP level.[15–18] The FEP levels decreased for all nine trainees sampled about six weeks after completion of training. However, five still had FEP levels greater than 0.89 μmol/L.

The blood lead level reflects very recent and current lead absorption. It is not an indicator of the total body burden of lead. The FEP can reflect lead absorption over the previous three to four months and is indicative of biological effects on heme synthesis, thus being a better indicator of the total body lead burden.[15,19,20]

The overall mean air lead concentration for all booths before the March 31 sampling was >2,000 $\mu g/m^3$ (Table 4). At this concentration, the OSHA permissible exposure level of 50 $\mu g/m^3$ for an 8-hour time-weighted average[14] was exceeded within 12 minutes of shooting. The mean exposure level determined on March 31, after final adjustments to the ventilation system, was 1,231 $\mu g/m^3$. At this level, the permissible exposure level is exceeded in 20 minutes of shooting. The trainees were on the range a mean of 73 minutes per session in *Period 1*, 39 minutes per session in *Period 2*, and 41 minutes per session in *Period 3* (Table 2), all well above the time limit at which the OSHA permissible exposure level was exceeded given the range's air lead concentrations.

In recent years, the use of handguns has increased rapidly as a recreational activity, resulting in the formation of many gun clubs whose members use indoor firing ranges frequently.[7,8]*** This, in turn, has resulted in the increased construction and use of indoor firing ranges. The NRA and AFA estimate that there are about 800,000 competitive pistol shooters and 70 million privately owned handguns in the United States.*** Two major builders of indoor firing ranges—Detroit Armor and Caswell International—estimated that they have built about 50 public indoor firing ranges each year for the past 5–10 years, with the number increasing each year.*** In addition, the National Institute for Occupational Safety and Health estimates that there are 16,000 to 18,000 indoor firing ranges in the United States.

Interviews conducted with members of shooting clubs in the Denver area, as well as telephone communication with the NRA and the AFA, revealed that pistol club members commonly practice weekly as a group for as much as an hour or two at a time, each shooting approximately 100 to 200 rounds of ammunition each time. Serious competitive shooters reported practicing up to five hours per week shooting about 500 rounds of ammunition per week. If other indoor firing ranges have air lead concentrations similar to those found in this study then, based on our data, frequent users would be at risk for developing elevated blood lead levels and adverse health effects from the lead exposure.

At the very least, users should be made aware by means of conspicuous warning posters that exposure to lead from indoor firing ranges can cause adverse health effects. Improvements of ventilation systems may help to decrease air lead concentrations. However, such measures are extremely difficult and expensive to undertake and often do not alleviate the problem.[6] Another alternative is to limit the amount of exposure a person could receive by determining from air monitoring how long a person could remain on the range per day before the person's exposure exceeded the OSHA standard. While it is not clear whether a high exposure to lead in a short period of time is biologically equal to lower exposure over a longer period of time, this approach to controlling lead exposure has been suggested.[6] For some persons this may be acceptable, but for others, especially members of pistol teams, such a time limit may be unacceptable. Another option that also may not be popular with the public is requiring the use of respirators while using the indoor firing range. A final possibility, and one that may have the most potential, is to use jacketed ammunition, shown in this and other studies to be effective in reducing the air lead level in indoor firing ranges.[6,21]

***Personal communication with the National Rifle Association (NRA), the American Firearms Association (AFA), Detroit Armor, and Caswell International on October 5, 1987.

ACKNOWLEDGMENTS

We gratefully acknowledge the National Institute for Occupational Safety and Health for funding the laboratory testing of blood samples; the law enforcement agency for allowing us to conduct the study; the trainees who participated in this study; and Jess Gibson, the firing range master. This paper was previously presented in part at the Centers for Disease Control's April 1988 EIS conference in Atlanta and also in the Epidemiology Late Breaker Session at the November 1988 APHA Convention in Boston.

Public Health Briefs

Accuracy of Women's Self-Report of Their Last Pap Smear

JOHN A. SAWYER, MD, JO ANNE EARP, ScD, ROBERT H. FLETCHER, MD, FEDORA F. DAYE, AND TONJA M. WYNN

Abstract: We compared interview data and physician records on when women last had a Pap smear in a sample of 98 rural Black women. We found 20 per cent of women could not accurately report on whether a Pap smear had been done within three years (sensitivity = 0.95, specificity = 0.47). Source of gynecological care and perceived barriers to obtaining a Pap smear but not education were associated with inaccurate reports. Self-report may be a misleading measure of Pap smear screening in comparable groups of women. (*Am J Public Health* 1989; 79:1036–1037).

Introduction

Women's own report of when they have had Pap smears is frequently the only source of information for clinicians who care for them, public health workers responsible for screening programs, and epidemiologists doing research.[1] However, some studies suggest that women may not recall accurately when they last received cervical cancer screening.[2–4] As part of a study examining patterns of Pap smear use among rural Black women, we assessed the accuracy of their recall of their last Pap smear and possible reasons for inaccurate self-report. We examined relations of source of care, educational level, and women's attitudes toward gynecological care to the accuracy of this recall.

Methods

We interviewed 149 Black women and reviewed records of their health providers in rural areas of three North Carolina counties. Approximately half the women were contacted by door-to-door canvasing of houses in low-income areas; the names of another third were provided by social workers in one county; the rest were friends and neighbors of the women referred by the social workers. During a structured, 30-minute home interview, two Black female interviewers asked the women about the date, place, and provider of their last Pap smear, their sources of medical care, attitudes toward gynecologic and preventive health practices, and perceived barriers to obtaining a Pap smear. After receiving informed consent from each woman, one of us (JAS) contacted providers by telephone to verify the women's reports on the date of their last Pap smear; a secretary or nurse provided the information after reviewing the woman's chart. We defined a "recent" Pap smear as one done within the past three years, based on the American Cancer Society's recommendation during the study period.[5]

We included in the questionnaire 17 questions about barriers to Pap smear use. We used a principal components factor analysis in a promax rotation to identify clusters of items (factors) that were related to each other.[6]

Results

Of the 149 women interviewed, 51 were excluded because they had had a hysterectomy (n = 28), had no source of medical care (n = 6), or were not listed on the rosters of any of the providers they named (n = 17). Our final sample of 98 women who had both a self-report and a provider report ranged in age from 16 to 75 years (mean 35), and in education from less than six to 16 years (mean 10.8; 22 per cent ≤9 years, 21 per cent 10 or 11 years, 57 per cent ≥12 years); their mean family income was $11,040 per year. Their demographic characteristics did not differ appreciably from 1980 census data for the three counties.

Women's self-reports correlated poorly with providers' reports on date of their last Pap smear (Table 1). Although there were errors in both directions, women usually overestimated how recently they had had a Pap smear. Using whether a Pap smear had been done in the past three years as a cutpoint, there was a 20 per cent error rate (Table 2). Women's self-report had a sensitivity of 95 per cent and a specificity of 47 per cent. Agreement between patient and physician was only fair (Kappa = 0.46).

As shown in Table 3, women seeing nurse practitioners were more likely to report accurately when their last Pap smear had been done than women seeing internists or family physicians. There were no clear differences in accuracy of reporting by age, income, education, or method of recruitment into the study.

Factor analysis identified two factors which we used to construct two variables involving six of the 17 potential barriers (the other 11 items showed no further discriminating

*Baseline
**Important = agreeing that at least two-thirds of the component items are important barriers to getting Pap smears

ability). The "pelvic examination barriers" factor contained three items: not liking to be examined by a male; pelvic examinations being unpleasant; pelvic examinations being embarrassing. The 30 women who felt that at least two of three of these barriers were important reasons why women did not get regular Pap smears gave less accurate reports than other women did. The factor labeled "trouble getting examinations" contained three items: seeing a doctor takes a lot of time; not wanting "to look for trouble"; meaning to get a Pap smear but "just not getting around to it". The 35 women who felt that at least two of three of these barriers were important reasons why women did not get regular Pap smears gave less accurate reports of when their last Pap smear had been done than did other women.

Discussion

A limitation of these data is that providers' records are not necessarily the "gold standard" for when the last Pap smear was done. It is possible that the medical record contained inaccurate data, or that dates were overlooked in the record review. If many Pap smear reports were overlooked, our estimate of the specificity of self-report would increase.

Women seen by internists and family physicians were least likely to report accurately about the recency of their last Pap smear. It may be that more of these women had pelvic examinations done for reasons other than Pap smears and either confused the term "pelvic examination" with "Pap smear" or assumed that a Pap was done routinely during every pelvic examination. Such confusion is important if women believe that they have had a Pap smear when they have not and may well prevent them from receiving one when they need it.

More than confusion, however, is involved; those women with inaccurate reports were also more likely to perceive significant logistical barriers to getting a Pap smear and to view pelvic examinations as embarrassing or unpleasant. Perhaps women with negative perceptions remember their last Pap smear more vividly. Vivid experiences are recollected as more recent, regardless of when they actually occurred and this may account for some of the inaccuracy of self-report.[7]

Somewhat surprisingly, a woman's educational level was not related to whether or not she recalled accurately when her last Pap smear had been done. Others also have found education to be unrelated to the accuracy of survey data.[4,8]

Although one may not be able to generalize these results, they highlight the danger of relying exclusively on self-reports for determining when a woman last received a Pap smear.

Nurse-Midwifery Practice in the United States, 1982 and 1987

CONSTANCE J. ADAMS, CNM, DRPH

Abstract: Surveys of certified nurse-midwives living in the United States were conducted on behalf of the American College of Nurse-Midwives for 1982 and 1987. Most of the respondents were providing prenatal and family planning care. The 1982 respondents conducted 1.8 percent of the deliveries that took place in the United States during 1982 and 1988 respondents conducted 2.5 percent of all 1987 United States deliveries. (*Am J Public Health* 1989; 79:1038–1039.)

Introduction

A certified nurse-midwife (CNM) is a registered nurse with advanced training in midwifery who possesses evidence of certification by the American College of Nurse-Midwives (ACNM). Nurse-midwifery practice encompasses responsibility for management of health care for women and newborns who do not have medical problems. Care for women is provided during the antepartal, intrapartal, and postpartal as well as the preconceptional and postconceptional phases of the reproductive cycle. Nurse-midwifery care occurs within a health care system that provides for medical consultation, collaborative management, and medical referral.[1,2]

United States resident CNMs were surveyed at the end of 1982 and in January 1988, to determine what services were being provided by these CNMs.

Methods

Survey questionnaires were mailed to 2,086 CNMs known to be living in the United States in 1982, 81.8 percent of the 2,550 ever-certified by the ACNM as of July 1, 1982, and to 3,846 CNMs known to be living in the United States in 1988, 97.1 percent of the 3,959 ever-certified by the ACNM as of October 1, 1987. An average of 360 registered nurses graduated from nurse-midwifery education programs accredited by the ACNM each year between 1982 and 1987. These graduates account for the additional CNMs surveyed in 1988. Participants were asked to respond to conditions and events pertaining specifically to 1982 and 1987, respectively. Identical questions about services provided were contained in both questionnaires. Usable questionnaires were returned by 1,584 (75.9 percent) of the CNMs in 1982 and 2,178 (56.6 percent) of the CNMs in 1988.

Results

A total of 1,065 (67.2 percent) of the 1982 and 1,527 (70.1 percent) of the 1988 respondents were practicing nurse-midwifery. Prenatal and family planning care were the services provided by the largest numbers of respondents (Table 1). Major increases in the proportions of respondents who conducted deliveries in hospital birth centers and who conducted multiple gestation deliveries were noted between 1982 and 1987.

The 937 respondents conducting deliveries in 1982 reported conducting 66,881 deliveries during that year, or about 1.8 percent of the 3,704,000 deliveries in the United States.[3] The 1,261 respondents who reported conducting deliveries in 1987 reported conducting 94,031 deliveries during that year, or about 2.5 percent of the 3,829,000 deliveries in the United States.[4] These CNM-conducted deliveries include deliveries conducted by nurse-midwifery students under the direction of CNMs.

The actual number of deliveries conducted by CNMs in the United States is unknown. The National Center for Health Statistics record numbers of deliveries conducted by midwives from information on birth certificates; however, deliveries include those conducted by lay midwives as well as CNMs. At least 10 percent of the 1982 and 1987 CNM respondents indicated on the questionnaire that they do not sign birth certificates for the babies they deliver.

Most deliveries conducted by respondents took place in hospitals. Only 12.5 percent (133) of the 1982 respondents and 10.7 percent (164) of the 1988 group conducted deliveries in homes; 12.6 percent (134) of the 1982 respondents and 11.1 percent (170) of the 1988 group conducted deliveries in out-of-hospital birth centers. Although only 64.8 percent (989) of the 1988 respondents conducted deliveries in traditional hospital settings compared with 71.4 percent (760) of the 1982 respondents, the percent who conducted deliveries in hospital birth centers increased from 30.0 (319) to 35.4 (541).

Participation in the care of some high-risk women during labor and delivery is suggested by the number of 1988 respondents who applied internal uterine pressure monitoring devices (1,063) or fetal scalp electrodes (988), rotated the fetus manually during labor (421), began oxytocin augmentations without physician consultation (122), interpreted electronic fetal monitoring strips (223), conducted breech delivery (141) or multiple gestation delivery (301), or removed the placenta manually when indicated (800). Some respondents also indicated that they repaired fourth degree lacerations or epitiotomy extensions (408), and cervical lacerations (552), as well as performed newborn intubation by laryngoscope (440) when indicated.*

For the purposes of both surveys, continuity of care was defined as care provided by an individual CNM, either alone or with CNM or physician colleagues, to a defined caseload of women through the antepartal, intrapartal, and postpartal phases of pregnancy. By 1987 at least 80 percent of the respondents working in all types of organizations reported providing continuity of care and at least 70 percent of the women they cared for received this care. Almost all of the respondents who worked in private practices provided continuity of care.

***1987: all who worked in type of organization whether primary, secondary, or tertiary work site.

Discussion

Nurse-midwifery continues to grow as a health profession in the United States. The number of nurse-midwives ever certified by the ACNM increased by 55.3 percent between 1982 and 1987. Although a lower percent of 1988 respondents conducted deliveries in traditional hospital settings, a much higher percent conducted deliveries in hospital birth centers. This is a reflection of more readily available options for birth sites within hospitals offered to women at low-risk of delivering obstetrical complications. About the same proportion of 1982 and 1988 respondents conducted home deliveries or deliveries in out-of-hospital birth centers.

Left-Handedness and Accident-Related Injury Risk

STANLEY COREN, PHD

Abstract: Self-reported injuries among left-handed and right-handed people were compared in a survey of 1,896 college students in British Columbia, Canada. Left-handers were more likely to report having an injury requiring medical attention during the last two years (OR = 1.89, 95% CI = 1.39, 2.58). Relative risk was highest for left-handed males when driving motor vehicles (OR = 2.35, CI = 1.25, 4.43). Regardless of handedness, males had slightly higher relative risks of injury than females. (*Am J Public Health* 1989; 79: 1040–1041.)

Introduction

Several reports show that the percentage of left-handers in the population decreases with increasing age,[1–4] with about 13 percent left-handedness in samples of 20 year olds, diminishing to 5 percent for those in their 50s, and to virtually 0 percent for samples age 80 and older.[1] Evidence suggests that this change in the frequency of left-handers is not explainable by historical trends in social pressure for right hand use.[1–3] In the belief that the absence of left-handers from the oldest age groups reflected higher risk of mortality for sinistrals, Halpern and Coren[5] conducted a study that suggested an association between left-handedness and shorter life-span. Using archival records from 2,271 deceased professional baseball players (excluding those with evidence for switched or inconsistent handedness), they found that the annual survival rate of right-handers exceeded that of left-handers by an average of about 2 percent. They suggested three possible causes:

- Left-handedness is sometimes associated with prenatal and perinatal stressors (e.g., low birthweight, prolonged labor, birth-related anoxias, Rh incompatibilities, and older mothers[1,6,7]) which may have sequelae that result in reduced survival ability.
- There are demonstrable associations between left-handedness, high levels of prenatal hormones, allergies, and immune disorders that may increase the risk of early mortality.[8,9]
- An environmental factor, the technological and behavioral bias toward dextrality, may be involved. Porac and Coren[1] collected numerous anecdotal reports that, because tools, machinery and even traffic patterns have been designed for the convenience of right-handers, left-handers may be more subject to accidental injuries which, individually or cumulatively, may result in reduced longevity.

The study reported below investigates the effects of handedness on injury risk.

Methods

A retrospective self-report procedure was employed. A sample of 1,896 students from the University of British Columbia (1,251 Caucasian, 567 Oriental, and 78 Black, American Indian or other, mean age 21.0, S.D. 5.62) were assessed in intact classroom units. All were tested for handedness using a four-item self-report inventory that assessed the hand used to perform common activities, specifically: drawing, throwing a ball, dealing cards and using an eraser on paper. This set of items has been shown to have a 97 percent concordance with behavioral testing and to be reliable over test-retest periods of a year.[1,10,11] In addition, individuals were asked to report if, in the previous two years, they had had any accidents in five categories of activity: when using tools or implements, while driving in traffic, when at home, when at work, or while participating in sports. Only accidents resulting in injuries that required medical attention were considered. No data were collected on medical events other than injuries, and medical confirmation of reported injuries was not sought.

Results

Analysis of the handedness patterns revealed 1,718 (90.5 percent) right-handers and 180 (9.5 percent) left-handers in this sample, which is similar to the usually obtained handedness distribution for this age group.[1]

Table 1 presents the distribution of injuries as a function of handedness as percentages and frequencies, while Table 2 presents estimates of relative risk in the form of odds ratios and their 95 percent confidence intervals. The relative risk of all injuries were elevated for left-handers. Although males tended to report more accident-related injuries than females overall (OR = 1.81, CI = 1.50, 2.18), left-handers had higher relative risks for both genders.

Among individuals reporting injuries in more than one category of activity, male and female left-handers were at higher risk.

Consideration of specific injury categories must be done with some caution, since we are partitioning the data into somewhat sparse groupings, and the relative distributions will be highly asymmetrical given the fact that the vast majority of the sample are right-handed and the bulk of the sample have not suffered from an injury in any given category. Table 2 shows higher relative risk of injury for left-handers in each of the five categories, although the only individual activity classification for which the elevation of risk is statistically significant is for injuries while driving a vehicle. The binomial test for all five comparisons in the same direction has $p = 0.04$. The same pattern appears with data segregated according to gender.

Discussion

These data suggest that overall (ignoring specific categories of activity) left-handers have increased risk of accident-related injuries, and higher risk of being injured in multiple categories of activity. Alternatively, the patterns seen could reflect a greater likelihood of left-handers to remember or report accidents, but we know of no data to suggest such a bias.

The most likely reason for the increased risk of injuries in left-handers comes from implicit and explicit biases of the environment toward maximal convenience of the right-

*Defined as (injured LH/uninjured LH)/(injured RH/uninjured RH)

handed majority. Everyday implements, such as scissors, gearshifts, and can openers, even the direction in which the threading of screws is angled, are biased toward right-handed use. Traffic patterns are designed to utilize the clock-wise turning bias of the right-hander. Many power tools, in their usual configurations, provide for free use of the right hand to manipulate materials, while restricting movements and utility of the left-hand, as can be seen in lathes, band saws, and some milling machines. Thus, to function in the right-handed world, the left-hander must either work with his non-dominant and less proficient right hand, or must adopt body postures and manipulation patterns which are at variance with the design of the machines. Such activities place the sinistral at a higher risk of suffering an accidental injury. This increased risk may be a significant factor in determining the longevity of sinistrals as a group (since injuries have been shown to be the underlying cause of death for more than 95 percent of individuals aged less than 55 years[11]) and may account for the relative rarity of left-handers in older age groups.

Deaths, Injuries, and Evacuations from Acute Hazardous Materials Releases

SUE BINDER, MD

Abstract: We examined reports from three surveillance systems of 587 acute releases of hazardous materials in 1986. These releases resulted in at least 115 deaths, 2,254 injuries, and 111 evacuations. Only eight (1 percent) of the 587 events were common to all three systems. Estimates of the public health consequences of hazardous materials releases could be improved by enforcing existing laws, modifying report forms, and validating collected information. (*Am J Public Health* 1989; 79:1042–1044.)

Introduction

The Superfund Amendments and Reauthorization Act of 1986 contains extensive provisions about emergency planning and the community's right-to-know about toxic chemical releases. A 1987 survey showed that information about public health consequences of such releases was generally not available at the state and regional levels (Sue Binder, unpublished data). Accordingly, we evaluated the three largest national sources of data that record deaths and injuries from acute chemical releases—the National Response Center (NRC), the Department of Transportation (DOT) Hazardous Materials Information System (HMIS), and the Acute Hazardous Events (AHE) data base. Our goal was to determine if these data bases could yield useful public health information. Characteristics of these data sources are discussed in the Appendix.

Methods

This assessment focused on incidents occurring in 1986, the last year for which complete data were available. All 1986 events coded in AHE and HMIS as having resulted in death, injury, or evacuation were obtained. Since NRC did not code evacuations in 1986, only events resulting in death or injury from hazardous materials releases were included. Events were coded as transportation-related if they appear in HMIS, were stated explicitly in NRC to involve a vehicle carrying a toxic chemical or to involve loading or unloading of a vehicle, or were coded in AHE either as occurring in transit or as occurring during loading or unloading and as involving a vehicle not in transit.

The data were converted to a Statistical Analysis System (SAS) format.[1] Events appearing in more than one system were identified and collapsed into one report, and then all reports were merged to form the Public Health Consequences data base. Descriptive analyses were conducted using SAS procedures.[1]

Results

The Public Health Consequences data base included 587 releases resulting in deaths, injuries, or evacuations (Figure 1). Only eight (1 percent) events appeared in all three data bases. These eight events all involved transportation (by definition, since they appear in HMIS) but were otherwise unclustered by type of chemical or in the numbers of people injured or killed.

Fifty-eight events resulted in a total of 115 reported deaths. Thirty-six of these events resulted in a single death each; the largest number of deaths in a single event was 14. Four hundred ninety-six events resulted in a total of 2,254 injuries. Three events resulted in over 100 injured persons each. Although 111 evacuations were identified from HMIS and AHE, the numbers of persons evacuated were missing for 75 percent of evacuations.

The chemicals involved in these incidents were unknown in 23 (4 percent) of the 587 events. For many events, only the class of chemical involved (e.g., corrosive liquid) was specified. Table 1 lists all chemical entries appearing more than five times in a data base.

Three hundred twenty-eight events, 56 percent of the events in the Public Health Consequences data base, involved an in-transit vehicle or an activity related to transportation (e.g., loading or unloading a vehicle). One hundred nine events represented crashes, derailments, and vehicular overturns—events that might occur in areas unprepared to deal with hazardous materials spills.

Discussion

The merged reports from the three systems indicate that there are an average of 1.6 hazardous materials incidents a day in the United States that result in either death, injury, or evacuation; almost once every three days, there is a release from a crash, derailment, or overturned vehicle that results in a similar outcome.

According to the Public Health Consequences data base, the number of people killed from hazardous materials releases in 1986 was 115 and the number injured was 2,254. Although these estimates are probably the most accurate so far, they represent the minimum number of persons killed and injured. A major reason is the mandated limits in scope of the

*Number of appearances is in parentheses. Only those appearing in the data bases five or more times are listed.

contributing systems. For example, HMIS excludes incidents involving intrastate carriers. A second problem is that the data bases probably do not capture all events falling within their mandate.[2,3] The fact that only eight of 595 events (1 percent) appear in all three data bases probably results both from the different areas of emphasis and failure to report by responsible parties.

In addition to incompleteness, the three component data bases have other limitations for evaluating public health impacts. The accuracy of the death and injury information is unknown, particularly for NRC and AHE. Reporting biases may result because certain industries or companies are more likely to report than others. Responsible parties may wish to present themselves in the best possible light, and may therefore tailor their reports accordingly.

The described characteristics of events in the data bases should be interpreted with caution. In particular, the results in Table 1 should not be interpreted as indicating the frequency or even the relative frequency with which a chemical was associated with deaths, injuries, or evacuations, since compliance with reporting requirements and accuracy of identification varies with different chemicals. The chemicals listed in Table 1 also reflect differences in emphasis among reporting systems. Natural gas releases, many from pipeline ruptures or occurring within private residences, were common in NRC. The lack of events involving natural gas, gasoline, and oils in AHE reflects its exclusion of chemicals not covered in Superfund legislation.

Although collecting data on hazardous materials spills is difficult, costly, and time-consuming, it could be improved by enforcing laws on incident reporting; obtaining more specific information about deaths, injuries, and evacuations; and validating collected information. Accurate and complete data on deaths, injuries, and evacuations resulting from acute hazardous materials releases could be used in many ways. Linking these data with information about commodity flows and geographic distributions of chemicals would allow calculation of rates to identify industries, types of facilities, activities, and areas of the country with higher risks of having releases with public health consequences. These rates would make it possible to generate hypotheses about why these events are occurring and to intervene appropriately. The identification of high-risk chemicals, facilities, and activities would also be of use to persons planning emergency response activities and to concerned communities. Although the available data are useful for providing minimum estimates of some of the public health consequences of unintentional hazardous chemical releases, improved surveillance would be an important step toward understanding the problem and, ultimately, preventing it.

APPENDIX

Description of Data Sources

The National Response Center (NRC), staffed and administered by the US Coast Guard on behalf of 15 participating federal agencies, has been collecting information on chemical releases and serving as a coordinating center for emergency response since 1974. The party responsible for the release is required to notify NRC about hazardous chemical and radiological releases exceeding certain quantities; hazardous materials releases from pipeline failures or cargo in transit resulting in specified outcomes, including death or serious injuries; and certain releases of toxic, corrosive or flammable gas, liquefied natural gas, or gas from a liquefied natural gas facility. By law, NRC must be notified by telephone within 24 hours for transportation-related events or as soon as practical for other events. Since this system is based on initial reports, the information is often incomplete. Much of the information is entered directly into a computer as long, uncoded fields of text. The data do not always indicate whether injuries or deaths resulted from the released chemical or from impact, as from a crash. Until recently, evacuations were uncoded. Data are generally neither verified nor updated.

The Hazardous Materials Information System (HMIS)—the main Department of Transportation (DOT) surveillance system for chemical releases since 1971—contains information about releases of hazardous materials in transit and during transportation-related loading, unloading, or temporary storage. By law, carriers must file written reports to HMIS within two weeks of a chemical release incident. These reports include information about the type of transport,

cause of the incident, container structure and failure, and deaths and injuries resulting from the cargo. DOT attempts to validate death and injury data. Specifically excluded from reporting requirements are releases of small quantities of certain consumer commodities, and releases from motor carrier firms doing solely intrastate business and from certain water transporters. Automobiles striking storage tanks and certain transportation-related spills at fixed facilities are also excluded.

The Acute Hazardous Events (AHE) data base was begun in 1985 and uses the NRC as its main source of data. However, data are also included from selected state governments, the Environmental Protection Agency (EPA) Region 7, some newspapers and wire services, and other sources. Information collected includes cause of event, activity taking place during the event, and type of property damaged. Attempts are made to eliminate deaths and injuries not caused by hazardous materials. Because emphasis was placed upon events involving chemicals covered by Superfund legislation and air releases from fixed sites, many events which appear in the NRC data base are excluded. AHE is maintained and augmented by EPA and its contractors, primarily Industrial Economics, Incorporated, and has been updated through 1986.[4] If events appear in more than one source, they are checked for consistency; otherwise, data are not validated.

Formaldehyde Exposures from Tobacco Smoke: A Review

THAD GODISH, PHD

Abstract: Reports of formaldehyde levels in mainstream, sidestream, and environmental tobacco smoke from nine studies are reviewed. Considerable disparity exists between formaldehyde production rates determined from mainstream-sidestream studies and those reporting levels in environmental tobacco smoke. Tobacco smoke does not appear to increase vapor-phase formaldehyde levels significantly in indoor environments, but formaldehyde exposure in mainstream smoke may pose a risk of upper respiratory system cancer and increase the risk of cancer in smokers. (*Am J Public Health* 1989; 79: 1044–1045.)

Introduction

Formaldehyde is a major oxidation by-product of combustion processes including tobacco smoking. It is produced in both the mainstream (MS), and sidestream smoke (SS), and has been reported in substantial levels in environmental tobacco smoke (ETS).

Formaldehyde levels in mainstream, sidestream, and environmental tobacco smoke reported by a number of investigators are summarized in Table 1. Reported studies vary in testing methodologies and expression of concentrations. Concentration units are those originally reported and those calculated and standardized by the author from original data, assuming a smoking rate of 35 ml/puff and 10 puffs/cigarette.

As seen in Table 1, formaldehyde concentrations in mainstream smoke[1–4] ranged from about 10 μg/cigarette to over 100 μg/cigarette. Differences in concentrations reflect differences in tobacco type and brand. Higher average concentrations reported by the Surgeon General in 1986[3] reflect those of regular non-filter cigarettes.

Sidestream vapor-phase formaldehyde concentrations also varied somewhat. Ayer and Yeager[5] reported 15–48 ppm. Hoffman's observations ranged from nondetectable to 34.2 μg/cigarette, with an average of 12.1 μg/cigarette for 16 different brands.[4]

Room or large chamber formaldehyde levels associated with environmental tobacco smoke[6–9] indicate that formaldehyde concentrations in such rooms are high. For example, in the studies of Howlett, *et al*,[8] one cigarette smoked in an environmental chamber caused the formaldehyde level to increase to 0.21 ppm within a half hour. Formaldehyde production rates calculated from ETS concentrations (Table 1) are substantially higher (one to two orders of magnitude) than those reported for MS, SS, and MS-SS combined.

The considerable disparity in formaldehyde production rates determined from MS-SS and ETS studies suggests differences due to methodologies employed in sampling and analysis. In the mainstream-sidestream smoke studies reported by the Surgeon General[2,3] and by Hoffman,[4] gas and particulate phase materials were separated by high-efficiency filtration. In studies by Weber, *et al*,[6] no attempt was made to remove particulate phase materials. Sundin[7] employed particulate phase filtration of unknown efficiency. Attempts to remove particulate phase materials in ETS samples were not reported by Howlett, *et al*,[8] and Klus, *et al*.[9]

In mainstream-sidestream smoke studies,[2–4] smoke samples were analyzed by the 2,4 dinitrophenylhydrazene-HPLC method which is specific for free formaldehyde. The chromatropic acid method[10] on the other hand was used in the studies of Weber, *et al*,[6] and Sundin[7]; it is likely to have been employed in the two other environmental tobacco smoke studies as well because it is the dominant method used to determine formaldehyde concentrations in air. In the chromatropic acid method, formaldehyde forms a stable addition product on sample collection in sodium bisulfite solution. On analysis, the addition product is destroyed yielding free formaldehyde. Any solution which contains free formaldehyde, a formaldehyde addition product, or organic compounds which produce formaldehyde on sulfuric acid destruction will test positive for formaldehyde.

On analysis with the chromatropic acid method, the particulate phase of tobacco smoke has been shown to contain appreciable quantities of formaldehyde.[5] This formaldehyde may be present as free formaldehyde dissolved in liquid water or it may be produced by the destruction of formaldehyde addition products and possibly other organic

Elimination of Cotinine from Body Fluids: Disposition in Smokers and Nonsmokers

NANCY J. HALEY, PHD, DANIEL W. SEPKOVIC, PHD, AND DIETRICH HOFFMANN, PHD

Abstract: We have evaluated differences in the elimination of cotinine, a major nicotine metabolite, in smokers who quit smoking and never-smokers who were exposed to environmental tobacco smoke (ETS) under controlled conditions. The mean biological half-life of cotinine in urine, collected from the nine smokers was 16.5 ± 1.2 h, in never-smokers exposed to ETS, 27.3 ± 1.9 h. Differences in the mode of uptake and absorption of nicotine and possible differences in nicotine metabolism may play roles in the clearance rate differences between smokers and nonsmokers. (*Am J Public Health* 1989; 79:1046–1048.)

Introduction

The elimination of nicotine, by smokers, users of other tobacco products, and by nonsmokers exposed to environmental tobacco smoke (ETS), is a variable metabolic process.[1–3] In a previous study, we observed that cotinine elimination in nonsmokers exposed to ETS tended to take longer than that seen in active smokers who quit smoking.[4] The slower clearance in nonsmokers of a terminal nicotine metabolite suggested that other tobacco smoke constituents or their metabolites might also remain in the bodies of nonsmokers for longer time periods.

Differences in the induction of hepatic and possibly pulmonary enzymes can play a role in the diverse metabolic rates observed between individuals.[5–11] Additionally, variations in the site and rate of absorption of nicotine can affect first pass metabolism by the liver and influence nicotine conversion as well as nicotine clearance.[8–10] Therefore we designed the current study to evaluate possible differences in the rate of cotinine elimination in smokers and ETS-exposed never-smokers.

Methods

Nine smokers between 23 and 38 years of age abstained from cigarette smoking for the duration of the study. Their prior smoking behavior ranged from self-reported use of six to 30 cigarettes per day. Smoking status was confirmed by urine cotinine concentrations. All urine voids were collected in four daily aliquots for five days beginning with cessation of smoking.

Ten nonsmokers who reported that they were never-smokers (26–45 years of age) were exposed to ETS for 80 minutes twice daily in two successive days in a specially constructed chamber. Five subjects were exposed at each time to the sidestream smoke produced by four Kentucky 1R1 Reference cigarettes which were continuously smoked throughout the exposure period. The chamber conditions have been described previously.[12] Briefly summarized, the chamber is 16.3 m^3 with six air changes per hour which corresponds to the average ventilation condition of offices in the United States. The pollution levels of selected smoke constituents were approximately 25 ppm CO, 0.9 ppm NO_x, and 160 $\mu g/m^3$ formaldehyde. These are considered high pollution levels. Urine samples were collected before exposure and in four daily aliquots as described for the smokers following cessation.

Each sample was analyzed for cotinine by radioimmunoassay (RIA) using specific antisera produced in rabbits.[13,14] Creatinine in urine was determined on a Kodak Ektachem 400 Clinical Chemistry Analyzer.[15] Creatinine excretion was used to normalize urine cotinine values.[14]

The volumes of smoke exhaled during smoking or ETS exposure are variable as well as the efficiency of lung clearance. These factors and the amount of matter expectorated or swallowed and absorbed from the digestive tract will affect bioavailability. In light of these variables, calculations of the dose of smoke taken up by subjects would be inappropriate. We have therefore assessed exposure by terminal cotinine half-lives ($t_{1/2}\beta$) estimated by linear regression of the log concentrations against time using an interactive computer program designed for the analysis of drug pharmacokinetics.[16]

Results

Data on the elimination of cotinine in the urine of smokers and ETS-exposed nonsmokers are presented in Table 1. The mean of the $t_{1/2}\beta$ for cotinine in the urine of the nine smokers was 16.5 ± 1.2 h. The coefficients of variation between subjects was 21 percent. Nonsmokers who were exposed to ETS had a mean $t_{1/2}\beta$ for cotinine elimination of 27.3 ± 1.9 h. The correlation coefficient for goodness of fit was r = 0.89 ± 0.02 in smokers and r = 0.90 ± 0.01 for nonsmokers exposed to ETS. For both smokers and nonsmokers, no correlation was observed between peak cotinine levels and elimination time. Nonsmokers had a substantially longer mean $t_{1/2}\beta$ of cotinine elimination (27.3) than smokers who quit (16.5).

Discussion

The results of this study support the concept that cotinine elimination can be more rapid in smokers than in nonsmokers who are exposed to ETS, and the earlier work by Kyerematen, *et al*, who observed that the $t_{1/2}\beta$ of nicotine in the urine of nonsmokers was more than twice as long as that of smokers.[17] Taken together, these observations could reflect a heightened carcinogenic potential of ETS in nonsmokers.

The slower clearance in nonsmokers of a terminal nicotine metabolite suggests that other tobacco smoke constituents or their metabolites may also remain in the bodies of nonsmokers for longer periods of time. Conceivably, this could increase the potential for endogenous formation of carcinogenic tobacco specific nitrosamines.[5] In considering

[a]Significantly different from smoker group ($p < 0.0007$).
[b]The confidence interval for the difference between means (10.8 h) was determined by first obtaining a pooled estimate of the variance.[26] Since both confidence limits were positive (95% CI = 1.4, 20.2), we concluded that the means between the groups were different.

the toxic burden imposed by exposure to cigarette smoke, it is important to note that sidestream smoke which is a major fraction of ETS contains higher levels of certain toxic cocarcinogenic and cancerogenic compounds than does mainstream smoke.[18] Before dilution with room air, some of these compounds are 50- to 100-fold higher in the sidestream smoke compared to their concentration in mainstream smoke.[19,20]

It is well documented that many compounds contained in tobacco smoke induce hepatic and pulmonary mixed function oxidases, yet the magnitude and duration of induction remains unclear.[18,21] It is conceivable that inhaled mainstream smoke and ETS might have varying effects on liver or lung oxidases due to the varying concentrations of smoke constituents. The importance of lung metabolism of inhaled xenobiotics is recognized.[22]

Differences between smokers and nonsmokers in the metabolism of drugs are substantial. Early studies by Hart, *et al*, have demonstrated enhanced drug metabolism in smokers by using anti-pyrine as an index of hepatic metabolism.[23] Powell, *et al*, reported a theophylline half-life intermediate between smokers and nonsmokers in exsmokers who abstained for three years.[24] Thus, differential rates of metabolism of nicotine in smokers and nonsmokers might be predicted from earlier work.

In our study, the $t_{1/2\beta}$ in never-smokers exposed to ETS under strictly controlled conditions was significantly longer than that seen for smokers. In most cases, the peak cotinine levels for smokers were much higher than in the ETS-exposed subjects, but no relation existed between peak cotinine levels and the $t_{1/2\beta}$ for cotinine excretion. It is probable, therefore, that elimination rate is not as greatly affected by dose as by method of exposure or subject metabolism.

A recent study by Jarvis, *et al*, concluded that differences in cotinine elimination do not exist between smokers and neversmokers.[25] In that study, nicotine pellets were ingested by five subjects of mixed smoking habits (cigars, cigarettes, and ex-smokers). Since such a protocol fails to allow for possible metabolic differences between smokers and never-smokers, ignores the lung as a metabolic site, and precludes the possibility of synergestic effects of any of the more than 3,800 constituents in tobacco smoke, we feel that the data of Jarvis cannot be compared to the current controlled study of cotinine elimination following active smoking or ETS exposure in smokers and never-smokers.

ACKNOWLEDGMENT

We would like to thank Caryn M. Axelrad and Stephen Colosimo for performing the cotinine analyses. We gratefully acknowledge Ilse Hoffmann's editorial assistance.

This work was supported by National Cancer Institute grants P01-CA 29580 and P01-CA 32617.

These data were presented, in part, at the International Symposium of Nicotine, Queensland, Australia, September, 1987.

Use of Smokeless Tobacco, Cigarette Smoking, and Hypercholesterolemia

LARRY A. TUCKER, PHD

Abstract: The primary purpose of this study was to determine the extent to which regular use of smokeless tobacco is associated with hypercholesterolemia (≥ 6.2 mmol/L) among 2,840 adult males. The confounding effects of age, education, physical fitness, body fatness, and other tobacco use were also examined. After adjustment, smokeless tobacco users were 2.5 times, heavy smokers were 2 times and mild/moderate smokers were 1.5 times more likely to have hypercholesterolemia than non-users of tobacco. Cigarette smokers did not differ significantly from users of smokeless tobacco regarding hypercholesterolemia. Users of smokeless tobacco were younger and less educated compared to non-users of tobacco, while smokers were less educated and less physically fit. (*Am J Public Health* 1989; 79:1048–1050.)

Introduction

National estimates indicate that at least 12 million Americans used some form of smokeless tobacco during 1985 and recent data show that 16 percent of males 12 to 25 years of age have used smokeless tobacco within the past year. An estimated 6 million persons use smokeless tobacco at least weekly and rates seem to be increasing, especially among adolescent and young adult males.[1]

The increased appeal and use of smokeless tobacco has generated considerable public health concern because research indicates that snuff and chewing tobacco can be significant health hazards. Most notably, dipping and chewing have been linked to oral cancer,[1–5] and numerous clinical studies have shown strong associations between smokeless tobacco use and noncancerous and precancerous oral conditions.[6–8]

Many of the health problems associated with tobacco use are a consequence of nicotine. Since the blood nicotine levels which result from smokeless tobacco use are similar to those from cigarette smoking,[9–11] the nicotine-related health effects of smoking would also be expected to result from using smokeless tobacco. Compared to nonsmokers, smokers tend to have elevated levels of low density and very low density lipoproteins and reduced levels of high density lipoproteins,[12–17] a lipid profile strongly associated with increased risk of atherosclerosis and coronary heart disease.[18–22] To date, only one unpublished study has been conducted to determine the effects of smokeless tobacco use on lipid metabolism.[23]

The present study was conducted to determine the extent to which use of smokeless tobacco contributes to hypercholesterolemia controlling for lifestyle and demographic factors, and to compare the effects of smokeless tobacco and cigarettes on hypercholesterolemia.

Methods

Subjects

A sample of 2,840 adult males with a mean age of 40.7 (SD = 10.8) was studied. Subjects were employees of over 25 different companies that participated in the Health Examination Program offered by Health Advancement Services (HAS), Inc. Approximately 70 percent of the men were married, 78 percent were White, and 73 percent had some college education. The median and modal annual gross family income was $25,000–$30,000.

All data were collected by registered nurses employed by HAS, Inc. Each subject was examined individually and privately for approximately 60 minutes after participating in an orientation and completing an informed consent form.

Instrumentation and Procedures

A written questionnaire was administered to assess demographic and life-style information, including use of smokeless tobacco and cigarettes. A Harpenden skinfold caliper was employed to assess subcutaneous fat at three body sites and the sum of the skinfold measurements along with age and gender were used to calculate the total body fat percentage of each subject.[24] Physical fitness was assessed using a step test, the Kasch 3-minute Pulse Recovery Test.[25] Approximately 10cc of blood was drawn from each subject and analyzed using the enzymatic method to determine serum cholesterol levels.[26]

Data Analysis

Subjects were classified as regular users of smokeless tobacco, mild/moderate smokers (1–20 cigarettes/day), heavy smokers (>20 cigarettes/day) or non-users of tobacco, according to their questionnaire responses. High blood cholesterol or hypercholesterolemia was defined as a total serum cholesterol level of 6.2 mmol/L or greater, consistent with the criteria of the National Cholesterol Education Program New Cholesterol Adult Treatment Guidelines.[27] The control variables were categorized as depicted in Table 1.

The associations between smokeless tobacco use, cigarette smoking, and hypercholesterolemia were measured by the odds ratio.[28] To control for potential confounders, Man-

TABLE 1—Smokeless Tobacco Use, Cigarette Smoking, and Hypercholesterolemia According to the Control Variables

Control Variables	col %	Tobacco Use				Hypercholesterolemia
		None	Smoke-less	1–20 cig	> 20 cig	6.2 + mmol/L
Total Group	100.0	76.7	3.3	15.1	4.9	18.6
Age (years)						
19–29	15.8	74.6 (6.1)	6.6 (13.8)	16.1 (2.8)	2.7 (16.7)	6.3
30–39	34.8	76.9 (13.5)	3.3 (9.4)	14.4 (21.3)	5.5 (14.8)	14.6
40–49	27.1	77.0 (20.7)	2.5 (31.6)	14.5 (33.6)	6.0 (37.0)	23.7
50+	22.3	77.1 (27.0)	1.9 (33.3)	17.1 (29.0)	3.8 (29.2)	27.9
Body Fat						
lean	13.5	75.3 (3.8)	4.5 (0.0)	14.7 (8.7)	5.5 (11.8)	4.8
moderate	58.4	77.7 (15.7)	3.2 (18.2)	14.6 (24.4)	4.5 (21.3)	17.4
obese	28.1	75.7 (29.2)	3.2 (33.3)	15.1 (34.7)	6.0 (33.3)	30.4
Education						
elem/hs	22.2	60.6 (17.3)	6.5 (18.4)	24.6 (21.0)	8.3 (27.1)	19.3
trade/voc	4.6	62.7 (13.5)	5.9 (14.3)	20.3 (37.5)	11.0 (23.1)	19.0
college	38.1	79.4 (15.1)	3.0 (16.7)	11.7 (25.0)	5.9 (15.5)	16.4
grad/prof	35.1	87.3 (18.9)	.9 (25.0)	9.6 (19.3)	2.2 (45.0)	19.8
Fitness						
good	21.7	87.1 (11.1)	2.9 (17.7)	8.0 (19.4)	2.0 (7.7)	12.0
average	30.2	80.4 (17.5)	3.6 (17.2)	11.4 (24.4)	4.7 (23.1)	18.9
poor	19.3	76.1 (23.9)	4.0 (9.5)	14.2 (28.6)	5.7 (25.0)	24.3
did not take	28.8	75.0 (17.6)	3.2 (29.2)	15.2 (20.7)	6.6 (28.9)	19.5

NOTE: Values in parentheses reflect the percentage of subjects within the subgroup who had hypercholesterolemia. For example, 33.3% of the subjects who were 50 years of age or older who used smokeless tobacco had hypercholesterolemia.
Body fat: lean = 10% or less body fat; moderate = 11–19% body fat; obese = 20% + body fat
Fitness: (age < 27) good = recovery HR ≤ 83 bpm; average = rec HR 84–99 bpm; poor = rec HR 100 + bpm
(age ≥ 27) good = recovery HR ≤ 87 bpm; average = rec HR 88-107 bpm; poor = rec HR 108 + bpm
didn't take = those subjects who chose not to take the step test.

tel-Haenszel summary risk estimates were employed.[29–31] Analysis of covariance (ANCOVA) for unbalanced data was employed to determine mean cholesterol differences between the groups after adjusting for age, education, fitness, and additional tobacco use.

Results

Of the 2,840 subjects, 93 (3.3 percent) were regular users of smokeless tobacco, 568 (20 percent) were cigarette smokers, and 10 (.35 percent) subjects reported regular use of both products. The serum cholesterol global mean was 5.30 mmol/L (SD = 1.08). As revealed in Table 1, regular use of smokeless tobacco was reported more often by the younger and the less educated subjects, and cigarette smoking was more prevalent among the less educated and the less fit. Hypercholesterolemia, measured in nearly 20 percent of the subjects, was more common in older, fatter, and less fit subjects.

Table 2 shows the estimated relative risk of hypercholesterolemia by tobacco use, including smokeless tobacco, without adjustment and with adjustment for age, education, physical fitness, and additional tobacco use. Control for differences in body fat had little effect on the results.

TABLE 2—Estimated Risk of Hypercholesterolemia by Use of Tobacco

Use of Tobacco	Variable Controlled	Hypercholesterolemia			
		N	%	RR_{mh}	95% CI
no use (n = 2,179)	none	377	17.3	1.00	—
smokeless tobacco (n = 93)	none	17	18.3	1.08	0.63, 1.85
	age, educ, fitness, & smoking			2.51	1.47, 4.29
cigarettes 1–20 daily (n = 429)	none	100	23.3	1.45	1.13, 1.86
	age, educ, fitness, & smokeless use			1.51	1.14, 2.00
cigarettes > 20 daily (n = 139)	none	34	24.5	1.55	1.04, 2.31
	age, educ, fitness, & smokeless use			1.98	1.29, 3.03

NOTE: Subjects who reported no use of tobacco were used as the reference group.

After adjustment, subjects who used smokeless tobacco regularly displayed 2 1/2 times the prevalence of hypercholesterolemia compared to non-users of tobacco. Heavy smokers had twice the prevalence, and light/moderate smokers had 1 1/2 times the prevalence of elevated cholesterol after controlling for the potential confounders (for the smokers, use of smokeless tobacco was controlled rather than cigarette smoking). There were no differences in risk of hypercholesterolemia between the smokeless tobacco and cigarette smoking groups.

Adjusted serum cholesterol means for the non-users of tobacco, smokeless tobacco users, light/moderate smokers, and heavy smokers were 5.29, 5.36, 5.38 and 5.52 mmol/L, respectively.

Discussion

Why smokeless tobacco users had 2 1/2 times the prevalence of hypercholesterolemia compared to non-users of tobacco is not clear. The substantial proportion of hypercholesterolemia among smokeless tobacco users could be the function of multiple factors and may not reflect cause and effect. Selection bias is possible, although unlikely (i.e., those with high blood cholesterol may choose to use smokeless tobacco more than the norm).

Other potential confounders, notably diet, could account for the smokeless tobacco/hypercholesterolemia relation. Moreover, because subjects in this study had relatively high socioeconomic status and educational levels, generalization to poorer, less educated groups will require additional study. The association between smokeless tobacco use and hypercholesterolemia is biologically sound, however, since smokeless tobacco acts as a vehicle to deliver nicotine to the system and results in blood nicotine levels similar to those attained by cigarette smoking.[1,11] Hence, it is plausible that increased levels of blood cholesterol result from dipping and chewing.

In conclusion, it is apparent from the present findings that the consequences of using smokeless tobacco may reach beyond the oral cavity. Although cause-and-effect conclusions are premature given the design of this study, carrying "a pinch between the cheek and gum" may lead to hypercholesterolemia and ultimately cardiovascular disease, as well as leukoplakias and oral cancer. Clearly, increased efforts directed toward elucidating the non-oral health effects of using smokeless tobacco are warranted.

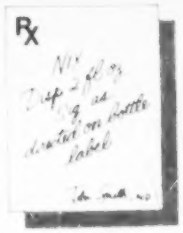
Nix FOR LICE
CREME RINSE
permethrin 1%



PEDICULICIDAL/OVICIDAL ACTIVITIES: *In vitro* data indicate that permethrin has pediculicidal and ovicidal activity against *Pediculus humanus* var. *capitis*. The high cure rate (97-99%) of Nix in patients with head lice demonstrated at 14 days following a single application is attributable to a combination of its pediculicidal and ovicidal activities and its residual persistence on the hair which may also prevent reinfestation.

INDICATIONS AND USAGE: Nix is indicated for the single-application treatment of infestation with *Pediculus humanus* var. *capitis* (the head louse) and its nits (eggs). Retreatment for recurrences is required in less than 1% of patients since the ovicidal activity may be supplemented by residual persistence in the hair. If live lice are observed after at least seven days following the initial application, a second application can be given.

CONTRAINDICATIONS: Nix is contraindicated in patients with known hypersensitivity to any of its components, to any synthetic pyrethroid or pyrethrin, or to chrysanthemums.

WARNING: If hypersensitivity to Nix occurs, discontinue use.

PRECAUTIONS:

General: Head lice infestation is often accompanied by pruritus, erythema, and edema. Treatment with Nix may temporarily exacerbate these conditions.

Information for Patients: Patients with head lice should be advised that itching, redness, or swelling of the scalp may occur after application of Nix. If irritation persists, they should consult their physician. Nix is not irritating to the eyes; however, patients should be advised to avoid contact with eyes during application and to flush with water immediately if Nix gets in the eyes. In order to prevent accidental ingestion by children, the remaining contents of Nix should be discarded after use.

Combing of nits following treatment with Nix is not necessary for effective treatment. However, patients may do so for cosmetic or other reasons. The nits are easily combed from the hair treated with Nix after drying.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Six carcinogenicity bioassays were evaluated with permethrin, three each in rats and mice. No tumorigenicity was seen in the rat studies. However, species-specific increases in pulmonary adenomas, a common benign tumor of mice of high spontaneous background incidence, were seen in the three mouse studies. In one of these studies there was an increased incidence of pulmonary alveolar-cell carcinomas and benign liver adenomas only in female mice when permethrin was given in their food at a concentration of 5000 ppm. Mutagenicity assays, which give useful correlative data for interpreting results from carcinogenicity bioassays in rodents, were negative. Permethrin showed no evidence of mutagenic potential in a battery of *in vitro* and *in vivo* genetic toxicity studies. Permethrin did not have any adverse effect on reproductive function at a dose of 180 mg/kg/day orally in a three-generation rat study.

Pregnancy: *Teratogenic Effects*: Pregnancy Category B. Reproduction studies have been performed in mice, rats, and rabbits (200-400 mg/kg/day orally) and have revealed no evidence of impaired fertility or harm to the fetus due to permethrin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the evidence for tumorigenic potential of permethrin in animal studies, consideration should be given to discontinuing nursing temporarily or withholding the drug while the mother is nursing.

Pediatric Use: Nix is safe and effective in children two years of age and older. Safety and effectiveness in children less than two years of age have not been established.

ADVERSE REACTIONS: The most frequent adverse reaction to Nix is pruritus. This is usually a consequence of head lice infestation itself, but may be temporarily aggravated following treatment with Nix. 5.9% of patients in clinical studies experienced mild temporary itching; 3.4% experienced mild transient burning/stinging, tingling, numbness, or scalp discomfort; and 2.1% experienced mild transient erythema, edema, or rash of the scalp.

DOSAGE AND ADMINISTRATION:

Adults and Children: Nix is intended for use after the hair has been washed with shampoo, rinsed with water and towel dried. Apply a sufficient volume of Nix to saturate the hair and scalp (especially behind the ears and on nape of the neck). Nix should remain on the hair for 10 minutes before being rinsed off with water. A single treatment is sufficient to eliminate head lice infestation. Combing of nits is not required for therapeutic efficacy, but may be done for cosmetic reasons or to meet school "no nit" policies. A nit comb is provided.

SHAKE WELL BEFORE USING.

HOW SUPPLIED: Nix (Permethrin) 1% (wt./wt.) Creme Rinse is supplied in plastic squeeze bottles that contain 2 fl. oz., weighing 56 g. (NDC-0081-0780-81).

Store at 15°-25°C (59°-77°F).

The Impact of Medicaid on Physician Use by Low-Income Children

MARGO L. ROSENBACH, PHD

Abstract: This study evaluated the determinants of physician use by low-income children, with an emphasis on the effect of Medicaid. Data are from the 1980 National Medical Care Utilization and Expenditure Survey. Regression analysis revealed that Medicaid children were more likely than both privately insured and uninsured children to visit an office-based physician. Also, Medicaid children with at least one visit to any setting had a higher number of visits than uninsured children. Such factors as age, health status, number of children in the family, educational status, and income also accounted for differences within the low-income population. The results suggest that access to physicians' services (including office-based physicians) can be increased by expanding Medicaid eligibility to uninsured low-income children and by improving private health insurance benefits among the underinsured. (*Am J Public Health* 1989; 79:1220–1226.)

Introduction

Children under age 21 comprise the single largest beneficiary group covered by the Medicaid program.[1] Congress has recognized the importance of this program by expanding Medicaid eligibility to previously uncovered groups of pregnant women and children under the Deficit Reduction Act of 1984, the Omnibus Budget Reconciliation Acts of 1986 and 1987, and most recently the Medicare Catastrophic Act of 1988. Whereas in 1964, 33 percent of the poor children and 15 percent of the nonpoor children had no physician contact in the previous two years, by 1981 the figures had decreased to 11 percent (poor) and 10 percent (nonpoor).[2,*] Average use by poor children increased from 2.3 contacts in 1964 to 4.8 contacts in 1981; nonpoor children went from 4.0 to 4.1 contacts.[2,*]

Not all of this large increase in physician use by poor children can be attributed to the Medicaid program, because of the concurrent efforts to stimulate the supply of services in low-income areas.[3] Moreover, it is misleading and inaccurate to assume that the low-income population is synonymous with the Medicaid population. For example, in 1980, 46 percent of the low-income children (less than 150 percent of poverty level) had Medicaid coverage for at least part of the year; 38 percent had private insurance for all or part of the year; and 16 percent were uninsured for the entire year.[4]

Previous research related to the effect of Medicaid on pediatric utilization is suggestive that Medicaid improves access to health care among low-income children, while simultaneously limiting their access to office-based physicians. Gortmaker concluded that Medicaid perpetuated a "two-tiered system" of care for children in Flint, Michigan.[5] Colle and Grossman support Gortmaker's view.[6]

Ongoing child health surveys in Rochester, New York, provide additional evidence on the effect of Medicaid on a child's regular source of care.[7–10] After the implementation of Medicaid, a substantial shift in source of care occurred in Rochester: from a physician's office to a clinic or health center.[9] Controlling for a wide range of factors associated with utilization, Wolfe[10] found that children on Medicaid were less likely to visit private physicians and more likely to use health centers and clinics in that city.

Descriptive data[2] clearly indicate that low-income children have experienced an increase in physician contacts since the implementation of Medicaid. However, given the sizable proportion of poor children not on Medicaid, aggregate data on the low-income population may mask utilization differences between those on Medicaid and those not on Medicaid.

This study was designed to evaluate the determinants of physician utilization by low-income children in the United States in 1980. Special emphasis has been given to the effect of Medicaid coverage on the probability and volume of use, as well as on the place of visit—physician visits in any setting versus those in a physician's office. A previous monograph[4] published by the National Center for Health Statistics presented descriptive data on the characteristics of low-income children and their health service use. This article presents the multivariate analysis, which determines the *independent* effect of many factors on the probability and volume of use.

Methods

This study uses data from the National Household Survey component of the National Medical Care Utilization and Expenditure Survey (NMCUES), a panel study of the United States noninstitutionalized civilian population in 1980. NMCUES gathered data on health status, accessibility and utilization of health services, charges and sources of payment, and health insurance coverage. The household survey consisted of 17,123 persons from about 6,000 randomly selected households. Each household was interviewed five times during 1980 and early 1981, roughly every three months. Methods have been described in detail elsewhere.[4]

The sample for this study includes children under age 18 living in families with incomes below 150 percent of the federal poverty level. Only children who were eligible for the survey for the entire survey period were included. This criterion excludes children who were born or who died during 1980, as well as those who were institutionalized for part of the year. Of the 5,074 children ages one through 17 who were eligible for NMCUES for the entire survey period, 1,409 were living in families below 150 percent of the federal poverty level. Of these, 654 had Medicaid coverage for all or part of the year.

Secondary data were obtained from two sources: 1) the Area Resource File[11] provided county level data on the supply of primary care physicians and the availability of emergency rooms; 2) a state-level exogenous price measure is based on work by the Urban Institute, to reflect the relative reimbursement within states under Medicaid and Medicare.[12]

The complex stratified multistage probability sample design used in the NMCUES required adjustments both in terms of sample weighting and variance estimation. All results have been weighted to produce national estimates.

Variances have been estimated using the Taylor series approximation. The SESUDAAN computer software[13] produced standard errors for means, totals, and proportions with adjustments for the complex sample design. The SURREGR program[14] handled regression estimation for continuous dependent variables. Standard errors for logistic regression were adjusted using a method developed by researchers at the National Center for Health Services Research.**

Dependent Variables

This study examines the effect of Medicaid on four measures of physician use: the probability and the volume of physician visits in an office setting and in any setting. The effect of Medicaid on physician access is expected to vary according to locus of care.[6,10]

The distribution of physician use is non-normal due to a concentration of those with no visits at one extreme and a small number of high users at the other extreme. The approach used in this analysis is to treat the use/nonuse decision as a dichotomous choice, based on the cumulative logistic probability function which predicts the probability of seeking care within the (0,1) range.[15] The volume equations include only children with one or more visits and are handled by weighted least squares regression, since the dependent variables are continuous measures. Because of the non-normal distribution of visits among users, the volume measures are log-transformed. Thus, the probability equation reflects the decision to initiate contact, while the volume equation captures the decision to make a single or multiple visits, a decision which involves the provider as well as the patient.[16]

For the purpose of this analysis a physician visit is defined as a face-to-face contact with a physician or a nonphysician working under the supervision of a physician. In addition, visits to nurse practitioners and physician assistants who were reported as "independent providers" are included. Otherwise, visits to independent providers (primarily chiropractors and optometrists) are excluded. Mental health visits are also excluded, as defined by the condition (mental disorder), the provider (psychiatrist, psychologist, social worker), or the setting (psychiatric clinic). Telephone contacts and physician visits to hospital inpatients are not counted.

Independent Variables

The first group of independent variables includes sociodemographic characteristics of the child and the family. Use decreases from infancy through the school-age years and then increases during adolescence.[5,10,17–20] To capture the nonlinear effects, age is specified in linear and squared form. Race is specified as a dummy variable equal to one if the child is non-White. Number of children in the family and educational status of the family (a dummy variable equal to one if no member of the family graduated high school) are also included in the model.

Income is specified as actual (reported) income in 1980. Price is defined as the out-of-pocket charge relative to the total charge for physician visits; however, this measure is restricted to the volume of use equations. An alternate proxy for "price" is the type of insurance, a measure of the effect of third-party coverage. Two dummy variables are used: private insurance for all or part of the year; and no insurance coverage during the entire year. The omitted category is Medicaid coverage during all or part of the year. Thus, the coefficients on the insurance variables reflect the difference between the specified type of coverage and Medicaid coverage (as measured by the intercept).

A regular source of care has been considered the second most powerful determinant of use, following measures of health status.[21] Because those who are high users of medical care may have a regular source of care precisely due to their high use, the probability equations do not control for presence of a regular source. The volume equations, however, test the effect of a regular source on the number of visits among those with at least one. A distinction is made between a physician's office as a regular source and all other settings. (The omitted category is "no regular source.")

Three variables are included in this study to capture provider availability:

- aggregate physician stock is measured as the ratio of office-based patient care physicians engaged in primary care, per 100,000 persons in the child's county of residence;
- the number of emergency rooms relative to the county's land area is considered a proxy for emergency room access; and
- a fee ratio measures the relative generosity of reimbursement levels under Medicaid and Medicare for a general practitioner.[12]

Previous research has shown that Medicaid participation is sensitive to average charges in the private market, as proxied by Medicare reimbursement.[22,23] Average Medicare reimbursement would no longer be an adequate proxy for changes in the private market because of a recent freeze on physician charge updates and continued erosion of Medicare fee inflation due to limits imposed by the Medicare Economic Index. However, the measure used here is from 1980 and may be considered a reasonable proxy for this study.

Three measures of health status are specified in the current study: 1) a combined measure of perceived health status and activity limitation at the beginning of the year; 2) the number of bed-days during the year; and 3) a hospitalization during 1980. This last measure is expected to be associated with more ambulatory care.[6,10,17]

Results

Descriptive Results

About one-fourth of the 63.9 million US children under age 18 in 1980 lived in poor and near poor families, defined as

TABLE 1—Insurance Coverage of Low-Income Children by Poverty Status: United States, 1980

Insurance Coverage	Number*	Percent

SOURCE: 1980 National Medical Care Utilization and Expenditure Survey.

families with incomes below 150 percent of the federal poverty level. Nearly one-half (46 percent) of the 16.8 million low-income children were covered by Medicaid for all or part of 1980; another 38 percent were privately insured for all or part of the year; and 16 percent were uninsured the entire year (Table 1). When added to the 3 percent with part year Medicaid coverage and 8 percent with private insurance part of the year, over one-fourth were uninsured for at least part of 1980.

Uninsured children were less likely than Medicaid and privately insured children to have a physician visit (Table 2), and averaged one visit less during the year than the other two groups. In addition, uninsured children with at least one visit had significantly fewer visits than each of the other two comparable groups. About one-half of low-income children had no visits to an office-based physician in 1980; among those with any visits, the average was 2.7 visits. No striking differences are noted by type of insurance coverage.

Extrapolating from reported charges, it is estimated that $1.4 billion was spent for physician visits by low-income children in 1980. The average charge per child with a charge was $150 for those on Medicaid part of the year or privately insured, but only $64 for the uninsured. The children on Medicaid the full year averaged $118. The average charge per visit was in the range of $34 to $38, except for the uninsured who averaged $24 per visit. Clearly, subsidized care accounts for a large amount of this difference. As one would expect, the reported average out-of-pocket expense for non-Medicaid children ($42) was more than triple the average expense for Medicaid children ($13). However, those on Medicaid part of the year had significantly higher out-of-pocket expenses than those covered by Medicaid the full year ($27 versus $10). This may be due in part to the "spend-down" requirements to qualify for a state's medically needy program under Medicaid.

Multivariate Results

The Appendix defines the variables included in the regression analysis and presents means and standard errors. Table 3 presents the econometric results for the probability equations and Table 4 shows the volume equations.

Insurance coverage has an interesting effect on the probability and volume of use. The coefficients on the two dummy variables for private or no insurance coverage reflect the probability or volume of use *relative* to that under Medicaid (the omitted category). Two results are noteworthy. First, Medicaid children had a higher *probability* of visiting an office-based physician than privately insured children and uninsured children (Table 3, equation 2). However, there were no differences according to insurance coverage in the *number*

of visits to office-based physicians among those with at least one visit (Table 4, equation 6). The second important result is that uninsured children had fewer visits overall (any setting), compared to other low-income children covered by Medicaid or private insurance (Table 4, equation 4).

As an alternative to the insurance variables, the price effect was measured as the percent of total charges paid out-of-pocket. As out-of-pocket charges increased, physician use decreased. Both total visits (any setting) and office-based visits were negatively related to "price." Use of office-based physicians was more sensitive to price than total use, suggesting a possible quantity-quality substitution.[24] In addition, non-Medicaid children were more price sensitive than Medicaid children.[24]

Physician use by low-income children has a U-shaped age effect: controlling for other factors, the predicted number of visits among those with at least one visit was highest for children ages one and two and lowest for those between ages nine and 11. The predicted number of visits began rising at age 11 through age 17.

White children had a higher likelihood of an office visit than children of other races. However, among those who had at least one visit, the number of visits was similar. Educational status of the family was not associated with the probability of a visit, but children in "more educated" families had a higher number of visits, both to an office setting and any setting. The number of children in the family was negatively related to physician use. Income was also negatively related to the probability of any use as well as the number of visits per user.

The presence of a regular source, either a physician's office or other place, had little or no effect on the volume of visits. As would be expected, those who reported a "regular place" as their usual source (e.g., clinic, health center, emergency room) had fewer visits to a physician's office. In general, however, these findings suggest that having a regular source of care is not associated with a higher level of use among low-income children.

The availability of office-based primary care physicians was negatively related to the probability of an office visit,

possibly because physicians may locate in areas of a county that are not low-income so that counties could have a high rate of physicians per capita but low rates in inner-city areas where the low-income are concentrated.[25] Alternatively, areas with a high ratio of office-based physicians per capita also tend to have more non-office-based facilities, such as outpatient departments, community health centers, and public health clinics. The availability of hospital emergency rooms was found to be a significant factor in the probability and volume of visits (any setting). Thus, as the availability of emergency rooms increases, use increases. This suggests that emergency rooms still may be an important source of care for low-income children despite efforts to develop alternate sources of care (e.g., community health centers).

Health status measures were the single most important group of variables that determine who uses physicians' services and how much. The direction of causality between bed-days and use is not clear because physician use may lead to bed-days or bed-days may lead to physician use. A hospitalization in 1980 was not a significant determinant of the likelihood of physician use, but as might be expected the volume of use was higher for those hospitalized during the year, indicating that ambulatory care complements inpatient use.

Table 5 displays the annual predicted utilization of Medicaid and non-Medicaid children according to health status. In all cases, the probability or volume of use was higher among Medicaid than non-Medicaid children. Medicaid coverage clearly increased the likelihood of an office visit. In addition, those with Medicaid coverage had more visits than uninsured children; compared to privately insured children, however, differences are small. Health status was a major factor in the probability and volume of use in all cases, yet the probability of a physician visit for uninsured children in fair or poor health was lower than the probability for Medicaid children in excellent or good health, all other things being equal.

Discussion

The preceding analysis has shown that Medicaid coverage increases access to office-based physicians, within the low-income population. The results obtained in this study suggest that previous studies which focus on the general population may obscure the effect of Medicaid on physician use by low-income children. Another important effect of Medicaid was on the number of visits among those with at least one visit. By lowering the relative price of a visit, Medicaid children made more visits than uninsured children, but not compared to privately insured children. These results are particularly important in light of recent Congressional initiatives allowing states to expand Medicaid eligibility to low-income children through age eight with incomes up to 100 percent of the federal poverty line, and infants under age one with incomes up to 185 percent of the federal poverty line.[26] The Medicare Catastrophic Act of 1988 *requires* states to cover infants under age one with incomes at or below 75 percent of the poverty line by July 1, 1989 and 100 percent by July 1, 1990.

The results of this analysis suggest that a policy to expand Medicaid eligibility to low-income uninsured children may be expected to have a relatively low *social cost*, that is, the cost of services resulting from a higher demand. It is estimated that a 50 percent decrease in the relative price of a visit would result in a 10 percent increase in use.[24] Applying this estimate to the average use of uninsured children with at least one visit, a 50 percent reduction in the relative price would result in an increase from 2.8 to 3.1 visits, on average. The *shifted cost*, however, could be somewhat higher if services paid for out-of-pocket, by other third-party payors, or through uncompensated care are paid by the Medicaid program as a result of expanded Medicaid eligibility. The costs could be partly offset by increased use of lower-cost office-based physicians.

This study also has implications for the financial access of privately insured low-income children. Low-income children covered by private health insurance may have lower use of office-based physicians' services, in part, because of the limited scope of benefits covered by their policies. Furthermore, income, educational status, and number of children may be important factors in health service use by the privately insured due to the indirect costs associated with taking a child to the doctor. This group had much narrower benefits for ambulatory care than for inpatient care, with coverage generally for inpatient care (86 percent) and inpatient physician visits (84 percent), but less frequently for office visits (44 percent), and rarely for dental visits (18 percent).[24]

TABLE 5—Predicted Annual Use* of Physicians' Services, According to Insurance Coverage: Low-Income Children, United States, 1980

	Insurance Coverage					
	Children in Excellent/Good Health and No Activity Limitation			Children in Fair/Poor Health or With an Activity Limitation		
	Medicaid	Privately Insured	Uninsured	Medicaid	Privately Insured	Uninsured
Probability of Physician Visit						
Any Setting	.74	.70	.64	.81	.77	.71
Office Setting	.53	.40	.42	.64	.51	.54
Number of Physician Visits						
Any Setting	2.64	2.60	2.23	3.98	3.92	3.37
Office Setting	2.05	1.86	1.81	2.67	2.43	2.36

*The predicted utilization figures were derived by multiplying coefficients from regression equations by the mean values for the total sample. Regression equations controlled for demographic characteristics, health status, economic factors, community resources, and organizational variables.

**For those with at least one physician visit.

***For those with at least one visit to an office-based physician.

SOURCE: 1980 National Medical Care Utilization and Expenditure Survey.

In this context, it is not surprising that privately insured low-income children had a lower probability of visiting an office-based physician than Medicaid children. However, among those with at least one office visit, there was no difference. Those with at least one visit are most likely the children with some coverage for office visits or else had individual arrangements with a physician. The children with no coverage for office visits may be considered worse off than Medicaid children, and perhaps, in terms of financial access to office-based physicians, they may be equivalent to uninsured children. At the very least, they are underinsured. Even those with coverage for office visits but with large deductibles may not have effective coverage if the level of the deductible results in full payment for the few visits made by the majority of the children each year. These problems may be compounded for the 8 percent of the low-income children who were privately insured part of the year and uninsured the remainder of the year.

Expanding private insurance benefits for office visits may lead to lower program costs for insurers. Privately insured children made an extremely high proportion of visits to hospital outpatient departments.[4] Office visit coverage may shift the locus of care from costly hospital-based facilities to less costly office settings. Furthermore, evidence suggests that office-based physicians provide more continuous care than hospital facilities and tend to hospitalize less often.[27] As a first step, Congress is considering legislation that would mandate employers with more than five employees to provide coverage for well-baby care through age one (among other benefits).***

These results should be qualified by several caveats. One limitation of this study is that the utilization measures do not account for the necessity or appropriateness of use. For this reason, it is not clear that "more use is better." Thus, to say that Medicaid children have more visits or a higher likelihood of an office visit should not be interpreted to mean that policies should necessarily strive to equalize physician use among Medicaid and non-Medicaid children, regardless of need. Rather, the goal should be equitable access, that is, "enough care to achieve . . . 'an adequate level of health care.' "[25]

A second caveat concerns the relevance of this study to the current environment. This study uses data collected in calendar year 1980. However, since 1980, many changes have taken place in the financing and delivery of health services. Within the private insurance market, many firms have sought to contain the cost of private health insurance by reducing benefits and/or increasing copayments. Others have turned to self-insurance to avoid compliance with state mandated benefit regulations. Additionally, preferred provider arrangements have been negotiated by private insurers as cost-containment mechanisms. The early 1980s saw extreme turbulence in the public sector, with retrenchments in the welfare rolls and hence in Medicaid eligibility. By the mid-1980s, Congress sought to extend Medicaid coverage to more low-income children and pregnant women. Other maternal and child health programs have continued to suffer from budget reductions (notably the MCH block grant). In other words, the 1980s may have brought about a widening in the disparities between low-income children covered by Medicaid and those who are uninsured or privately insured. Additional research is required based on a more recent database to test the generalizability and sensitivity of the results obtained in this study.

New 800 Number for National AIDS Information Clearinghouse

The National AIDS Information Clearinghouse (NAIC) now has *one toll-free number*. Callers can obtain reference assistance and order publications simply by dialing 1-800-458-5231.

NAIC, a free service of the US Department of Health and Human Services, Public Heath Service, Centers for Disease Control, is the only centralized source for comprehensive information about HIV/AIDS programs, services, and materials. This national clearinghouse serves health professionals, state and local AIDS program managers, and others responsible for educating the public about HIV and AIDS.

NAIC's toll-free number puts callers in touch with reference specialists who are available to answer questions, make referrals, and suggest publications pertaining to HIV infection and AIDS. NAIC specialists are available to talk with Spanish-, French-, and Creole-speaking callers.

The Clearinghouse is also a direct source of *free*, Government-approved HIV and AIDS educational materials—brochures, posters, point-of-purchase displays, and more. Selected materials are available in Spanish. Orders for bulk quantities or single copies of publications can be placed through the Clearinghouse's toll-free telephone line.

Callers can speak with NAIC reference specialists and order publications by dialing 1-800-458-5231, Monday through Friday between 9 am and 7 pm (eastern time). Requests for information can also be made by writing: NAIC, Box 6003, Rockville, MD 20850 (FAX: 1-301-738-6616).

Risk Factors Associated with Participation in the Ontario, Canada Doctors' Strike

RICHARD L. KRAVITZ, MD, MSPH, MARTIN F. SHAPIRO, MD, PHD, LAWRENCE S. LINN, PHD, AND ERIKA S. SIVARAJAN FROELICHER, PHD

Abstract: To identify factors associated with participation in the 1986 Ontario, Canada doctors' strike, we surveyed 1,028 physicians; 69 percent responded, of whom 42 percent participated in the strike. Risk factors for participation included income greater than $135,000, being a surgeon or gynecologist, having previously "opted out" of the Ontario Health Insurance Plan, being professionally dissatisfied, being politically conservative, favoring political activism by physicians, holding a positive view of the social consequences of extra-billing, and perceiving family, associates, patients and the public to favor the strike.

Eighty percent of strikers, but 32 percent of non-strikers, met criteria we established for four strike-prone groups: the "economically rational," the "ideologically committed," the "professionally disaffected," and the "socially malleable." Respondents belonging to one or more of these groups were much more likely to have participated in the strike (64 percent vs 17 percent). Strategies to deal with physician militancy should address the multiplicity of motives that appeared to have influenced doctors in Ontario. (*Am J Public Health* 1989; 79:1227–1233.)

Introduction

Health care initiatives in many countries in recent years have led to the emergence of new forms of medical practice and new kinds of professional relationships, some of which have undermined the relatively unrestricted autonomy that practitioners previously enjoyed. The professional press in the United States and elsewhere has recently reported on doctors in conflict with insurance companies, hospitals, health maintenance organizations, and governmental agencies.[1–3] At least 17 times since 1960, physicians in Western countries have translated discontent with health systems into organized work slowdowns and strikes. These activities have generally been directed against governments for the purpose of extracting financial concessions, preventing undesired structural changes in health care delivery, or preserving professional independence.[4,5] Although associated with certain medical[6,7] and moral costs,[8] they have often produced definite gains for participants.

Although physicians dissatisfied with their conditions of practice have a variety of individual and collective responses available to them,[9] strikes and work slowdowns are the most visibly disruptive. Several studies have described factors that affect physician satisfaction and dissatisfaction,[10–12] but the characteristics that differentiate physicians willing to strike from those unwilling to strike have not been examined.

Health care in Ontario, Canada is financed jointly by the provincial and federal governments and is administered through the Ontario Health Insurance Plan (OHIP). Physicians are paid on a fee-for-service basis according to a schedule negotiated annually by the Ontario Ministry of Health and the Ontario Medical Association (OMA).[13] Throughout most of the OHIP's history, physicians were permitted to "opt out" of the plan, thereby gaining the option to "extra-bill" their patients at rates of their own choosing (and presumably higher than those allowed by the provincial fee schedule). This situation ended in 1984, when Parliament directed that provinces stop allowing extra-billing or else forfeit a substantial portion of their federal funding. Along with other provincial medical societies and the Canadian Medical Association, the OMA protested, on the grounds that a ban on extra-billing would infringe upon the right of physicians to negotiate a contract directly with their patients, and ultimately would undermine the quality of care, by eliminating a safety valve for occasions when the government failed to provide adequate support to the system.

When the Ontario legislature prepared to implement the federal mandate by introducing the Health Care Accessibility Act (1986), the OMA asked its members to strike. Beginning on June 12, 1986 and ending 23 days later, the strike not only failed to avert the ban on extra-billing, but was widely viewed as a public relations disaster for physicians.[14,15]

To understand how misgivings about changes in the system were transformed into action, and to identify risk factors for participation in the strike, we surveyed a broad sample of Ontario physicians. Based on expectancy-value theory[16] and prior studies of physicians in the US and Canada,[17–19] we hypothesized that they would be influenced by economic self-interest, ideologic orientation, professional work satisfaction, and perceptions of how peers, patients and others viewed the strike.

Methods

In late April 1987, we mailed a self-administered questionnaire to a probability sample of 1,170 physicians in active practice in Ontario as of June 12, 1986. Physicians were selected in a systemic fashion from the 1986 *Ontario Medical Directory*.[20] Subjects from communities with fewer than 30 physicians were oversampled to assure adequate representation of rural practitioners. In addition to identifying factors, physicians were questioned as to duration and intensity of participation in the strike; political affiliations; attitudes as measured on a series of scales dealing with government intervention, physician activism, medical altruism, professional autonomy, and work satisfaction; prior history of "opting out" and "extra-billing"; perceptions of the consequences of extra-billing, the Health Care Accessibility Act, and of the strike itself; and degree of support for the strike among co-workers, family, staff, patients and the public.

Subjects missing more than 50 percent of the items used to form a scale were eliminated from analyses of that scale. Although the attitudes of strikers and non-strikers on Likert-type scales were initially compared using mean scale scores, scores were ultimately dichotomized about the midpoint of the scale for ease of interpretation[21]; the main results were unchanged. Complete scaling information is given in the Appendix.

Statistical Analysis

We determined strike participation rates within demographic, professional, and attitudinal subgroups of physicians. Differences were assessed with Chi-square tests; confidence intervals for differences in participation rates were calculated using standard methods.[22]

Based on the hypothesis that economics, ideology, professional satisfaction, and perceptions of how others viewed the strike would be important determinants of strike behavior and, after noting the results of the univariate analyses, we selected nine variables for entry into three logistic regression models. Model I was the full model (see Table 2 for specification of variables). In addition to the full model, two partial models were developed in order to estimate the effects on strike participation of professional characteristics along with general attitudes not directly related to the issues at hand (Model II), and of professional characteristics alone (Model III). Adjusted odds ratios and 95 percent confidence intervals were derived from the logistic coefficients and their standard errors.[23] Reweighting the regression models to adjust for oversampling of rural physicians had no significant impact upon the results.

In the third part of the analysis, we hypothesized that striking physicians would fall disproportionately into four overlapping groups: the "economically rational," the "ideologically committed," the "professionally disaffected," and the "socially malleable." We developed criteria defining membership in the groups using variables that were both theoretically important[16,24] and statistically significant in the logistic regression analysis. Finally, we computed strike participation rates among risk-group members and calculated the sensitivity and specificity of the group classification scheme for identifying strike participation in the study population.

Results

After follow-up, 712 subjects (69 percent) returned completed surveys. Respondents and non-respondents did not differ by specialty, community size, or gender. The median age of respondents (43 years) was slightly greater than that of Ontario physicians as a whole (41 years).[25]

Eighty-percent of study participants were male; 92 percent were White. Forty-six percent of subjects were in general or family practice, 11 percent in internal medicine or pediatrics, 12 percent in surgery or obstetrics-gynecology, 8 percent in psychiatry, and 23 percent in other specialties including radiology, anesthesia, dermatology, rehabilitation, and emergency medicine. Thirty-three percent of the sample worked in solo private practice, 31 percent in group practice and the remainder in public or community hospital-based practice (11 percent), academic medicine (13 percent), residency (9 percent) and various other settings including industry and penal institutions (3 percent).

The percentage of respondents participating in the strike was 42 percent. Among strike participants, 50 percent withheld services for greater than 21 days, while the rest returned to practice-as-usual after one to 21 days. Withdrawal of services was highly selective. For example, 100 percent of "striking" surgeons reported some reduction in office visits, but only 62 percent closed their offices to patients visits altogether; 76 percent stopped performing elective surgical procedures, but only 6 percent stopped making hospital and emergency room visits.

Striking and non-striking physicians were similar in age, sex, and religion, but those who were not White, whose first language was other than English or French, who had high family incomes, were married or who had children were more likely to strike (Table 1). Those not White (95 percent Asian) and those whose first language was not English or French struck at higher rates regardless of practice setting or specialty. Being married, however, was associated with a greater likelihood of striking only among physicians with family income less than $110,000 per year. Strikers and non-strikers were also distinguished by specialty and practice setting, but not by community size. Working more than 50 hours per week was associated with greater participation in the strike only among non-surgeons.

Strike participation was greater among those who considered their political thinking "right-of-center" or "far-right" (Table 1) and among physicians who identified with the Progressive Conservative Party rather than with the Liberal Party or the New Democratic Party.* Other characteristics that were associated with increased strike participation included high valuation of professional autonomy, individualistic notions of responsibility for health care, opposition to government-sponsored social programs, and agreement that physicians could "properly" participate in leafleting, demonstrations, and various kinds of strikes (Table 1).

As expected given the nature of the dispute, behaviors and attitudes related to extra-billing were strongly associated with strike participation. Physicians who had "opted out" or "considered opting out" of OHIP were more likely to strike than those who had not. Although the vast majority of respondents (86 percent) viewed preservation of the right to extra-bill as socially desirable, those who disagreed were much less likely to strike (Table 1).

Ontario Medical Association members were more likely to have struck than non-members (Table 1), as were those who "usually or always agreed" with the OMA's official positions on medical and political issues.* Physicians who generally believed that colleagues, spouses, office staff, patients, and the public were in favor of the strike were more likely to have participated in it themselves. Finally, the 24 percent of subjects who were less than "moderately satisfied" with their professional work participated in the strike more frequently.

Logistic regression provided adjusted estimates of the effects of nine selected variables on strike participation. In the full model (Model I, Table 2), behaviors and attitudes related most directly to the strike had the strongest associations: the odds of striking for physicians who had opted out of OHIP in the past, viewed extra-billing as socially beneficial, or perceived others to have supported the strike, were three to eight times higher than for those who had not. In this model, having a high family income, practicing alone or in a non-hospital-based group, and having a positive view of physician activism also were related to striking.

In Model II, which contained practice characteristics and general attitudinal factors, but excluded variables prox-

*Full model
†Model containing professional characteristics and general attitudes only.
‡Model containing professional characteristics only.

imate to the issues at hand (Table 2), high income surgical speciality, non-institutional practice, political position, and professional dissatisfaction were significantly associated with striking. Little change in the adjusted odds ratios for practice characteristics was observed when general attitudes were dropped (Model III, Table 2), except that the point estimate of the odds ratio for surgeons rose to 3.0. The full model correctly distinguished strikers from non-strikers 78 percent of the time.

Based on the expectation that strike participants would arise disproportionately from specific segments of the physician population, we tested the proposition that strikers were more likely than non-strikers to meet defined criteria as "economically rational," "ideologically committed," "professionally disaffected," or "socially malleable" (Table 3). Physicians who generally viewed doctors' strikes as "probably or definitely improper" were excluded from each of the four groups. Eighty percent of strikers, but 32 percent of non-strikers belonged to one or more of these "high risk" groups. Of 368 physicians (52 percent) belonging to one or more of these four categories, 64 percent struck, compared to just 17 percent of the 354 subjects not-so-classified.

TABLE 3— Categories of physicians at "high risk" for participation in the Ontario doctors' strike.

High-Risk Category	Criteria
Economically rational (n = 121; strike participation rate = 77%)	1. History of opting out of OHIP or considered opting out of OHIP, and 2. Family income greater than $110,000.
Ideologically committed (n = 240; strike participation rate = 68%)	1. Right-wing or right-of-center in political thinking, and 2. Progressive Conservative Party affiliation, and 3. View of extra-billing as socially beneficial.
Professionally disaffected (n = 136, strike participation rate = 65%)	1. Dissatisfaction with aspects of ability to enlist system resources for the benefit of patients, and 2. Pessimism about the future of medicine.
Socially malleable (n = 254, strike participation rate = 72%)	1. Ontario Medical Association member and 2. Perception that either colleagues, patients, or both supported the strike.

Discussion

Medical autonomy in the United States is under fire.[1,2,26] The threat comes not only from patients' changing attitudes, grounded in consumerism and litigiousness, but also from the new-found strength of third party payers and the rise of bureaucratic forms of medical practice.[27] Under these conditions, strikes by US physicians may become increasingly common. This study suggests that, contrary to public impressions, practicing physicians in Ontario are politically

heterogeneous, constituting a collection of diverse interests rather than a professional monolith. Nonetheless, many strikers shared certain common characteristics.

The announced intent of the Ontario government to ban extra-billing in May 1986 served as a focal point for the mounting discontent of many Ontario physicians. The strike drew support from nearly all regions and specialties, but failed to enlist the participation of a majority. Strikers differed from non-strikers demographically, professionally, politically, and socially. Since the survey was conducted after the strike, some of these associations may represent an effect of the decision to strike (or its covariates) upon the attitudes or characteristics in question rather than the other way around. However, many of the variables of interest (e.g, practice setting, income) are relatively stable over time and are unlikely to be influenced by the fact of strike participation.

The increased rate of strike participation among physicians who were not White was modest and might be discounted, but the association between being a native speaker of a foreign language and striking was more robust. Analysis of written comments submitted by these physicians revealed that many of them were immigrants from eastern Europe or Asia who harbored deep resentment against government involvement in medicine. British physicians expressed similar feelings.

Conservative ideology was consistently correlated with increased strike participation, whether measured by party affiliation, self-description, or agreement with conservative values. Similarly, a study of British general practitioners[28] found that doctors who provided the Medical Guild with undated resignations from the National Health Service (to be used as a threat during negotiations over reimbursement) were more likely to endorse traditional medical role conceptions, reject self-sacrificing attitudes, and oppose government involvement in medical practice.

Variables were selected for logistic regression analysis based on *a priori* hypotheses and on the strength of their simple and stratified associations with striking. The results accorded with a general formulation of expectancy-value theory,[16] in which persons weigh the consequences of action and relevant social norms in deciding how to behave. Views on extra-billing provided the most direct measure of physicians' beliefs about the consequences of the proposed legal ban. Prior OHIP status reflected physicians' stake in the issues at hand, a factor of importance in prior studies of physician activism.[28] To flesh out the model, we tried to determine subjects' prior conceptions of the likely consequences of going on strike (for the practice of medicine and for the public health), but the proposed scale was not sufficiently reliable (Cronbach alpha < 0.5).

Several factors appeared to modify the effects of perceived consequences and subjective norms in our subjects. Respondents who disapproved of political expression by physicians were unlikely to have participated in the strike, no matter what their politics. Whether these notions derived from ethical considerations or reluctance to breach authority is unclear. Practicing surgery or gynecology was associated with striking, but the odds ratio declined by approximately 50 percent as attitudes and prior OHIP status were added to the logistic equations, suggesting that their high participation rate was largely due to their more often holding attitudes associated with striking and to their having a larger economic stake in the issues.

In order to present our findings in a format useful for policy, we restructured the logistic results to produce a classification scheme that made theoretic sense. "Economically rational" physicians stood to benefit directly from the continued ability to extra-bill and had high family incomes. For them, the expected benefits of preserving extra-billing exceeded the expected costs of striking. High-income physicians could also be expected to endure a loss of practice income (as during a strike) with less hardship.

"Ideologically committed" physicians were politically conservative, identified with the Progressive Conservative Party, and considered the social benefits of extra-billing to outweigh any conceivable costs. They viewed the motives of the Ontario government with suspicion, disputed the notion that extra-billing denied the indigent or elderly access to care, and viewed extra-billing as a "safety-valve" primarily for preservation of autonomy and not just to enhance income.

The "professionally dissatisfied" doctors in our study expressed dissatisfaction with one or more aspects of their ability to provide care under the constraints of Ontario's insurance plan and were pessimistic about their professional future. They may have joined the strike as an expression of alienation from their work and as a reaction to the perceived hostility of legislators, bureaucrats, and journalists.

The final risk category included physicians who may have been influenced to strike by their medical leadership, their professional peers, or their general social environment. These "socially malleable" doctors belonged to the Ontario Medical Association and perceived colleagues or patients as favoring the strike. Membership in the OMA was included in the criteria list for "social malleability" only because *non-members* were highly *unlikely* to strike. Since we did not measure others' actual views, we cannot exclude the possibility that physicians' perceptions were biased; nor can we be sure that subjects did not select the company they kept based partly on medical politics. Nevertheless, they may have participated in the strike partly out of deference or loyalty to respected persons or groups. Given the demonstrated importance of social influence in diverse populations, it would be surprising if physicians emerged as an exception.

Although non-respondents to our survey were similar to respondents along lines of gender, specialty, and community size, we lack information about their income levels, workloads, practice settings, and political affiliations and attitudes. However, the distributions of many of these variables among respondents are remarkably similar to those reported previously in population surveys of Ontario physicians.[19,25] Furthermore, our estimate of the proportion of physicians participating in the strike jibes well with those of others.[29] Lastly, the magnitude of any differential response would have had to be extremely large to influence the direction of most of the findings. For example, even if all 316 non-respondents were in solo or group practice and only 20 percent of them struck (vs 50 percent among responding solo/group practitioners), the overall strike rate for solo/group practitioners would remain 13 percent higher than for institutionally based physicians. If, on the other hand, all 316 non-respondents practiced in institutional settings and 50 percent of them struck, the overall rate difference would still favor solo/group physicians by 12 percent.

Physicians' strikes are not inevitably harmful to society. They "can serve as an important catalyst in converting a rigid and conservative health system into a more flexible democratic organization for all its workers,"[5] and may be ethically justifiable in some situations.[30,31] Nevertheless, as quasi-violent means to even socially desirable ends, strikes frighten

the public,[7] arouse ethical qualms in physicians, have the potential for producing adverse health outcomes, and ought to be avoided if possible.

Once the federal government mandated an end to extra-billing, the Ontario strike may have been inevitable. It is possible, however, that the strike might have been attenuated by early, targeted attention to the groups of physicians described here. Some combination of fee increases, assurances of continued clinical autonomy, concrete improvements in the health care system, and more accommodating dialogue with the OMA might have reached some members of the "economically rational," "ideologically committed," "professionally disaffected," and "socially malleable" groups, respectively. In any case, this study indicates that strikers could be identified by their membership in specific risk groups, each characterized by specific attributes and motives. As physicians in the United States as well as Canada begin to exercise their collective power in defense of socio-economic and technical autonomy,[27] greater understanding of the diverse interests within the profession may facilitate more skillful management of doctors' strikes and other manifestations of this emerging medical militancy.

APPENDIX

Description of Scales

1. *Economic—Welfare Liberalism*[17]
   Internal consistency in current population: alpha = .63
   Scale: 5 = strongly agree—1 = strongly disagree
   Items:
   a) It is the responsibility of society, through its government, to guarantee full employment.
   b) The government should play a bigger part in the economic life of the nation in order to distribute income more equally.
   c) Poverty could almost be done away with if we made certain basic changes in our social and economic system.
   d) [Canada] needs a complete [socialist] restructuring of its basic institutions.
2. *Professional Autonomy (newly derived)*
   Internal consistency in current population: alpha = .63
   Scale: 5 = strongly agree—1 = strongly disagree
   Items (R = item is reversed for scoring purposes):
   a) The federal government has no business trying to influence the specialty choices of medical students.
   b) The best thing about medicine in the past, as compared to today, is that you could be your own boss.
   c) There are too many controls on the medical profession that interfere with taking care of patients.
   d) Government should have a strong voice in determining the organizational form of medical practice. (R)
3. *Physician Activism*[17] *(modified for this study)*
   Internal consistency in current population: alpha = .83
   Scale: 5 = definitely proper—1 = definitely improper
   Items:
   a) Placing activist pamphlets or posters in waiting rooms.
   b) Wearing buttons with activist slogans while on duty.
   c) Participating as doctors in marches or other demonstrations.
   d) Participating in strikes against individual hospitals or clinics.
   e) Participating in strikes against the provincial or federal government.
4. *Medical Altruism (newly derived)*
   Internal consistency in current population: alpha = .53
   Scale: 5 = strongly agree—1 = strongly disagree
   Items (R = item is reversed for scoring purposes):
   a) Medical care is a right, not a privilege.
   b) A physician is morally obligated to treat people of all races, religions, sexual orientations, and personal habits, regardless of his or her own preferences.
   c) It is the responsibility of society, through its government, to provide everyone with best available medical care, whether he can afford it or not.
   d) Things work best when people concern themselves mainly with their own welfare and let others take responsibility for themselves. (R)
5. *Social Benefits of Extra-Billing (newly derived)*
   Internal consistency in current population: alpha = .76
   Scale: 5 = strongly agree—1 = strongly disagree
   Items (R = item is recorded for scoring purposes):
   a) Extra-billing never presented a significant barrier to poor people seeking medical care.
   b) With extra-billing abolished, the provincial legislature is already at work seeking ways to further restrict the independence of physicians.
   c) The elderly and indigent are *more* likely to receive needed medical care now that extra-billing is prohibited. (R)
   d) The ban on extra-billing will inevitably lead to more complete government control of medicine.
6. *Impression of How Others Viewed the Strike (newly derived)*
   Internal consistency in current population: alpha = .82
   Scale: 3 = in favor of, 2 = neutral towards, 1 = opposed to
   Items:
   a) Physician partner or closest medical colleague.
   b) Spouse.
   c) Office staff.
   d) Nurses with whom I work (on average).
   e) My patients (on average).
   f) The general public (on average).
7. *Physician Satisfaction*[12] *(last 3 items newly derived)*
   Internal consistency in current population: alpha = .83
   Scale: 5 = extremely satisfied—1 = very dissatisfied
   Items:
   a) Your contact with other physicians.
   b) Your relationships with non-physician health professionals.
   c) Degree to which your work is educationally stimulating.
   d) Manpower resources available to you.
   e) Diversity of patients you see (age, sex, types of problems/disease).
   f) Patient volume.
   g) Your ability to derive personal gratification from patient care.
   h) Salary/income.
   i) Your role in making administrative decisions.
   j) Your ability to meet the needs and demands of patients.
   k) The degree of status and prestige associated with your work.
   l) Your ability to remain knowledgeable and current.
   m) Opportunities for advancement and future success.
   n) Your ability to provide patients with care of the highest quality.
   o) Your ability to hospitalize patients when you consider it necessary.
   p) Your ability to obtain clinically indicated diagnostic tests on your patients.

ANA Opts for New Structure and Broader Membership Plan

The American Nurses' Association (ANA) House of Delegates, at its recent annual meeting, adopted a flexible new plan to alter the structure of the nation's largest professional nursing organization and its 53 constituent state nurses associations. New by laws adopted by the house will broaden the ANA membership and alter its governance structure and relationships with other national organizations.

Most of the changes come from recommendations made by the ANA Commission on Organizational Assessment and Renewal (COAR), following 18 months of study, proposal development, and consensus building by the commission with ANA's constituency, its elected and appointed officials, and other national nursing groups and the profession at large. Some of the changes wrought by the new by laws include:

- Multi-state nurses associations and organizations of US nurses overseas can become constituent members of ANA whereas only state nurses associations were eligible in the past.
- State nurses associations can have organizational affiliates or members. These may include specialty nursing organizations meeting the qualifications set forth in the by laws. The rights of these affiliates will be prescribed by the individual SNAs, and be limited to the state level of the association.
- Individual members of SNAs must be registered nurses. A proviso requires the ANA House of Delegates to determine the membership rights, responsibilities, and privileges of these individuals at the time SNAs move to admit technical nurses as members.
- At the close of next year's House of Delegates meeting, a Congress of Nursing Practice and a Congress on Nursing Economics will be formed—to focus on long-range policy development, standard setting, program development, and evaluation in their area of expertise, as well as addressing emerging health care and nursing issues on an ad hoc basis.

Other matters addressed by the 1989 ANA House of Delegates included: seating of ANA councils and organizational affiliates in the House of Delegates; establishing a separately incorporated center to serve the ANA credentialing programs; retaining authority for setting standards related to nursing education, practice and service; expansion of joint ventures with other nursing organizations; enhancing non-dues revenue and developing incentive programs to build membership; provision for increases in dues assessment paid to ANA; and receiving a progress report on plans and activities to relocate the association's headquarters to Washington, DC.

The ANA is the national professional association representing the nation's two million registered nurses through its 53 constituent state and territorial nurses associations. The 1990 ANA House of Delegates will meet June 15–20, 1990 during the association's biennial convention in Boston.

Induced Abortion and the Risk of Subsequent Ectopic Pregnancy

Victoria L. Holt, MPH, Janet R. Daling, PhD, Lynda F. Voigt, BS, Barbara McKnight, PhD, Andy Stergachis, PhD, Joseph Chu, MD, MPH, and Noel S. Weiss, MD, DrPH

Abstract: This study assessed the effect of legal induced abortion on ectopic pregnancy risk by using a comparison group of reproductive-age women who were at risk of becoming pregnant during the same time period the women with ectopic pregnancy conceived. Cases were members of Group Health Cooperative of Puget Sound who were hospitalized for ectopic pregnancy from October 1981 through September 1986 (N = 211). Controls were randomly selected members matched to cases on age and county of residence (N = 457). All subjects in this analysis had had one or more prior pregnancies.

Eighty-eight cases (41.7 per cent) and 177 controls (38.7 per cent) had a history of one or more induced abortions. The relative risk of ectopic pregnancy associated with one abortion was 0.9 (95 per cent confidence interval 0.6, 1.3), adjusted for age, county, reference date, religion, gravidity, age at first pregnancy, lifetime number of sexual partners, and miscarriage history. Among women with two or more prior pregnancies, the risk associated with two or more abortions was 1.2 (0.6, 2.4). Controlling for pelvic inflammatory disease and use of intrauterine devices did not alter these risks. We conclude that legal abortion as performed in the US since 1970 has little or no influence on a woman's risk of ectopic pregnancy in subsequent pregnancies. (*Am J Public Health* 1989; 79:1234–1238.)

Introduction

The rate of ectopic pregnancy in the United States tripled between 1970 and 1983, from 4.2 to 12.6 per 10,000 women between 15 and 44 years of age.[1,2] Although improved diagnostic capabilities may be responsible for enhanced case finding, it seems likely that this increase in rates reflects a substantial actual increase in ectopic pregnancy incidence.[3] During the same time period, the incidence of induced abortions rose from 5 per 1,000 women 15 to 44 years in 1970 to 23 per 1,000 in 1983.[4,5] This parallel increase suggests the possibility that induced abortion may predispose to a subsequent ectopic pregnancy. A possible basis for such a predisposition could be fallopian tube scar tissue formation associated with salpingitis, since induced abortion has the potential to introduce salpingitis-causing organisms via contaminated instruments or cause organisms already present in the vagina to ascend.[3,6]

The results of recent US research concerning the association between induced abortion and ectopic pregnancy have been generally reassuring, but not conclusive. Chung's prospective cohort study in Hawaii found no increased risk.[7] In case-control studies, however, both Daling, *et al*, and Levin, *et al*, found a weak association between a history of multiple abortions and ectopic pregnancy, but the studies were small and chance effects plausible.[8,9] Both case-control studies compared cases to controls chosen from women delivering a liveborn child. Such a control group may underrepresent women with a history of induced abortion and create an artifactual relation between abortion and ectopic pregnancy in the absence of a real association.[10] The present study sought to eliminate this potential bias by the use of randomly selected reproductive-age women as a comparison group.

Methods

Case Identification

Eligible cases were all women members 18 years of age or older who were hospitalized with the diagnosis of ectopic pregnancy at Group Health Cooperative of Puget Sound hospitals between October 1, 1981 and September 30, 1986. Group Health Cooperative is a prepaid health care cooperative founded in 1947; it serves over 320,000 residents of western Washington State. Cases were identified using a computerized hospital discharge system that has been in use at Group Health Cooperative since 1972.

Each patient's primary care physician at Group Health Cooperative was sent a letter describing the study and asking permission to contact the patient. If he or she consented, the Group Health Cooperative Research Department mailed a letter with a self-addressed card to the subject, asking her to return the card to indicate whether or not she wished to participate. If she agreed to participate, the interviewer telephoned her to explain what her participation in the study would involve, answer any questions about the study, and arrange for the interview. Subjects signed consent forms and medical records releases at the interview. Of the 396 patients identified as eligible from hospital records, primary care physicians refused permission to contact 11. In addition, 39 patients refused to participate, and nine could not be reached. A total of 337 cases were interviewed, 85.1 per cent of those eligible (Table 1).

An estimate of the date a case conceived her ectopic pregnancy was considered her "reference date." All questionnaire information gathered pertained to exposures and characteristics prior to that date.

Control Identification

Controls were women of child-bearing age identified

TABLE 1—Subject Response by Case Status

Total Subjects Identified	Cases		Controls	
	N = 396	(%)	N = 1139	(%)
Interviewed	337	(85.1)	893	(78.4)
MD refusal	11	(2.8)	32	(2.8)
Patient refusal	39	(9.8)	168	(14.7)
Lost to follow-up	9	(2.3)	46	(4.0)

from Group Health Cooperative membership files. They were selected randomly, and matched to cases by age and county of residence. Ages were matched as closely as possible: within one year for the majority of subjects, extending to a maximum of five years for one set. Two potential controls were initially selected for each case, and if either of them was unreachable or declined to participate, further controls were selected. Efforts continued to enlist the participation of everyone who was initially selected. Consequently, in many instances more than two controls were matched to each case. Controls were assigned a reference date which was the midpoint of the three-month quarter containing the reference date of the case to whom they were matched (Table 2). To be eligible, a control had to be a Group Health Cooperative member at her assigned reference date. After a potential control was identified, her primary physician was notified. If the physician gave permission for her to be contacted, the same sequence of events was followed as for cases. Of 1,139 potential controls identified, 32 were not contacted due to physician request. When contacted, 168 women refused to participate, and 46 could not be reached. Eight hundred ninety-three control subjects were interviewed, 78.4 per cent of those eligible (Table 1).

Potential controls whose husbands or partners were sterilized were excluded from consideration if the sterilization had not been reversed. Women with a history of hysterectomy or no sexual activity for the 12 months preceding the reference date were also excluded from the control group. Also, women four to nine months pregnant at the reference date, and therefore not at risk of being diagnosed as having an ectopic pregnancy, were identified from Group Health Cooperative prenatal files and excluded as potential control subjects.

Data Collection

Ninety-nine per cent of the cases and 95 per cent of the controls were interviewed in person. During the interviews, which lasted an average of 56 minutes, respondents were queried concerning their reproductive, contraceptive, sexual, and medical histories, past hygienic practices including douching, and demographic and lifestyle characteristics. For each induced abortion, information obtained included gestational age, abortion method, medical setting where the procedure was performed, and whether infection occurred after the abortion.

To decrease the possibility of recall bias, month by month calendars of all contraceptive, reproductive and other important personal events were formulated and discussed by interviewers and all subjects. The interviewers were not blinded to the subjects' diagnoses, but when 24 cases and 66 controls were contacted again and reinterviewed with selected questions by a different interviewer, the responses were in agreement 97 per cent of the time for cases and 95 per cent for controls.

As part of a substudy on the validity of self-reported data, the medical records of all subjects who reported intrauterine device (IUD) use and a random sample of 20 per cent of other subjects were reviewed. Information obtained from medical charts included history of induced abortion. Interview and chart information agreed for 264 of 285 subjects for whom there was information from the chart (Table 3).

Analysis

For this analysis, cases (n = 23) and controls (n = 14) with a prior ectopic pregnancy were excluded. Also excluded from both groups were women without a pregnancy prior to reference date (65 cases and 263 controls), and women who had had an induced abortion before 1970 when abortion became legal in Washington State (two cases and 15 controls). All surgically sterilized women (35 cases and 153 controls) were excluded since they already had their fallopian tubes occluded, the hypothesized means by which induced abortion could predispose to an increased risk of ectopic pregnancy. Seven cases with nontubal ectopic pregnancies (six ovarian and one abdominal) were excluded. Five subjects (one case and four controls) were excluded due to missing data for key model variables. Two hundred ten cases and 453 controls remained for analysis.

Multiple logistic regression analysis was performed to control for matching variables (age, reference date, county) and to adjust for the confounding effect of other exposures.[11] Relative risks approximated by odds ratios were estimated by the method of maximum likelihood. Significance tests were based on the chi-squared approximation for the likelihood ratio statistic, and 95 per cent confidence intervals were based on the standard error of coefficient estimates and the normal approximation.

Dichotomous variables considered in the analysis were education (≤12 years vs >12 years), marital status at refer-

ence date (married, living as married or steady partner vs separated, divorced, or never married), ever-use of oral contraceptives, ever-use of Dalkon Shield or other IUD, current use of contraceptives, history of douching, miscarriage, gonorrhea, pelvic inflammatory disease (PID), and endometriosis. Two dichotomous variables were used for abortion history: one abortion vs none, and two or more vs none. Categorical variables included cigarette smoking (never, former, current), race (Black, White, other), religion (Catholic, Protestant, other, none), age (<20 years, 20–24, 25–29, 30–34, 35+), family income (<$15,000 per year, $15–30,000, >$30,000), reference year (1981–82, 1983–84, 1985–86), duration of barrier contraceptive use (no use, <2 years, 2–4 years, 5+ years), lifetime number of sex partners (one, 2–4, 5+), age at first regular intercourse (<18 years, 18–20, 21+), age at first pregnancy (<20 years, 20–24, 25+), and gravidity (one, two, three or more pregnancies).

Results

A higher percentage of cases than controls were Black (Table 4). Cases were also more likely to have a family income under $15,000 per year and to be current cigarette smokers. Average age at first regular intercourse and age at first pregnancy were lower for cases than controls, while the cases had had a higher lifetime number of sexual partners. Case women also reported a history of PID more frequently than control women, with 4.7 per cent of cases and 3.3 per cent of controls reporting a first episode of PID occurring after their first abortion. IUD ever-use was slightly greater among cases, due to their higher frequency of Dalkon Shield IUD use. Controlling for either PID history or IUD usage did not alter the risk of ectopic pregnancy associated with induced abortion. Cases were more than three times as likely not to be contracepting at reference date than controls (Table 4), but abortion history did not differ between women using and those not using contraception at reference date (Table 5).

Eighty-eight cases (41.7 per cent) and 177 controls (38.7 per cent) had had one or more induced abortions (Table 6). The relative risk of ectopic pregnancy associated with a history of one induced abortion was 0.9 (95 per cent confidence interval 0.6, 1.3) when adjusted for age, county of residence, reference date, religion, age at first pregnancy, number of pregnancies, lifetime number of sexual partners, and prior miscarriage history. Among women with two or more prior pregnancies (125 cases and 288 controls), the relative risk for two or more abortions was 1.2 (95 per cent CI = 0.6, 2.4).

Method of abortion, gestational length, and site where abortion was performed did not vary appreciably between cases and controls (Table 7). Cases reported pain for longer than one week after last abortion twice as often as controls, but this result could be due to chance. The mean time from last abortion to reference date was 64.8 months for cases and 68.8 months for controls.

Discussion

We found little if any increased risk of ectopic pregnancy associated with prior induced abortion. Generalization of these results to a population outside the United States or to one for whom induced abortion is not legal may be misleading since the manner in which abortions are performed may influence their effect on ectopic pregnancy risk.

Ascertainment of abortion exposure was based on subject self-report in this study. If selective underreporting by cases or controls existed, our estimates of relative risk may be biased. Information from the substudy on validity of self-reported data indicates a small amount of underreporting

of prior induced abortion status may have been present. Four per cent of cases and 2 per cent of controls denied a history of induced abortion during their study interview, but had such a history noted in their medical charts. If the chart information more closely represents actual abortion history, our results may be a slight underestimate of the true effect. In our study, 42 per cent of cases and 39 per cent of controls stated they had had one or more induced abortions, whereas a study of Washington state multigravida women giving birth in 1984 and 1985 found that 25.6 per cent reported a prior abortion on the birth certificates in a random sample.[12] Since our subjects reported a considerably higher frequency of abortion history, we may be somewhat reassured that substantial underreporting does not exist.

Recent US studies have disagreed about the extent to which abortion is a risk factor for subsequent ectopic pregnancy. In case-control studies, Daling, *et al*, and Levin, *et al*, both found a modestly elevated ectopic pregnancy risk in women with a history of one abortion (Daling RR = 1.4, Levin RR = 1.3), and a somewhat higher risk associated with multiple induced abortions (Daling RR = 1.8, Levin RR = 2.6).[8,9] However, in both studies the number of cases with two or more abortions was small and associations found could have been attributable to chance. Moreover, both researchers chose controls delivering a child at a time comparable to the case's ectopic pregnancy surgery, and by definition this control group did not include women who conceived but chose to terminate that pregnancy. The cases had no similar termination opportunity, as ectopic pregnancy usually manifests itself before a woman's knowledge of her pregnant status. Since women terminating pregnancies have been estimated to have a higher frequency of past abortions than do women carrying a full-term pregnancy, use of these control groups may have led to an artificially elevated ectopic pregnancy risk associated with prior abortion.[10] Although Daling, *et al*, attempted to correct for this bias by limiting their study to married women and controlling for contraceptive use at time of conception, we believe our use of a more general population control group is a more direct way to address this issue.

Chung's Hawaiian study followed a large cohort of women who had abortions performed in the four years immediately following legalization of the procedure in Hawaii in 1970. The researchers found little increased risk associated with abortion in general (RR = 1.2), but did find a strong association (RR = 5.1) between abortion and ectopic pregnancy in women who had post-abortion infection or retained products of conception.[7] In our study, post-abortion infection was identified by 2.3 per cent of the cases and 5.1 per cent of the controls who had a history of abortion, and was not a risk factor for subsequent ectopic pregnancy. One difference between our study and Chung's which may account for this discrepancy is the time period during which the study was conducted. As years pass since the legalization of induced abortion in Washington State in 1970, physician expertise in the performance of the procedures may be improving, thereby minimizing risk to the patient. The abortion procedure itself has also changed over the past two decades, with decreased use of dilatation and curettage (used in 10 per cent of our cases' and 11 per cent of our controls' last abortion) and increased use of less traumatic suction procedures (used in 81 per cent of cases' and 77 per cent of controls' last abortion).

In conclusion, this study yields no evidence that legal abortions performed since 1970 in our study population led to increased risk of ectopic pregnancy in subsequent pregnancies. We found no increase in risk in women with a history of one induced abortion (RR = 0.9), and the slightly increased risk we found to be associated with multiple abortions (RR = 1.2) could easily have been due to chance. Providing that the

Group Health Cooperative experience is similar to that of other populations within the US, these results argue that the increasing rate of induced abortions is not an important factor in explaining the sharp rise in ectopic pregnancy incidence in this country in the past two decades.

Yale University to Strengthen Its Public Health Program

A Yale University committee released a report in mid-July recommending to President Benno C. Schmidt Jr. a strategy to strengthen teaching and research in public health at the institution. The committee, which deliberated over six months, gathered information from faculty, students, alumni, and local and national leaders in public health. The basic goals of the committee's recommendations are to establish a leadership role for Yale in the arena of public health. In its report, the committee emphasized that the public health profession plays a critically important role in protecting and improving the physical and mental well-being of the nation.

Specifically, the committee recommended that the Department of Epidemiology and Public Health remain a department of the School of Medicine within which it will retain its status as a school for purposes of accreditation. To signal clearly the comprehensive mission of the department, the Committee suggests that the department be renamed the Department of Public Health. Burton H. Singer, PhD, professor of public health and the head of the biostatistics division, was named to a two-year term as Chairman of the Department of Public Health and Associate Dean for Public Health. A native of Chicago, Dr. Singer received BS and MS degrees from Case Institute of Technology in 1959 and 1961, respectively. In 1967, he received a PhD degree in statistics from Stanford University; he joined the Yale faculty in 1985. Dr. Singer succeeds Jan A. J. Stolwijk, PhD, who has completed seven years as Chairman and previously announced that he would return to full-time teaching and research.

Other recommendations for public health at Yale that the president will consider include:

- Establishing a standard committee within the School of Medicine to ensure ways of integrating teaching and research programs in public health with medicine;
- Allocating new resources to the department for the purpose of renovation of facilities and the recruitment of faculty;
- Strengthening the process for recruitment and admission of students;
- Strengthening ties between the Department of Public Health and other interested units of the University;
- Renovation and expansion of public health facilities at 60 College Street for public health programs;
- Increasing the size of the faculty by recruiting up to eight new faculty members;
- Strengthening the Master of Public Health Program by reorganizing the student admission process and focusing on the development of leaders in the field.

Founded in 1915, the present Department of Epidemiology and Public Health is a nationally accredited school of public health. It is among the oldest of 23 such schools in the United States and one of the few that is a department within a medical school.

The Relationship of Smoking and Ectopic Pregnancy

ARDEN HANDLER, DRPH, FAITH DAVIS, PHD, CYNTHIA FERRE, MA, AND TIMOTHY YEKO, MD

Abstract: A case-control study, using data abstracted between 1983 and 1987 from a large perinatal registry, was conducted to explore the relationship between smoking and ectopic pregnancy. Women with ectopic pregnancy (n = 634) seen at University of Illinois Perinatal Network Hospitals were compared to women who were delivered of a single live-born infant (n = 4287). Adjusted for age and race, women who reported smoking during pregnancy had a greater than twofold risk of ectopic pregnancy (Odds Ratio = 2.5, 95% confidence interval = 1.9, 3.2) compared to women who never smoked. The estimated relative risk rose from 1.4 (95% CI = 0.8, 2.5) for a woman smoking fewer than 10 cigarettes a day to 5.0 (95% CI = 2.9, 8.7) at one and a half or more packs of cigarettes per day (p-value for trend <0.001). Although further basic and epidemiologic research is necessary, the observed dose-response relation strengthens the argument that smoking may be a causal factor in the development of ectopic pregnancy. (*Am J Public Health* 1989; 79:1239–1242.)

Introduction

Although ectopic pregnancy is a relatively uncommon occurrence, its incidence has quadrupled from a rate of 5/1000 live births in 1970.[1] Simultaneously, maternal mortality rates from other causes have fallen, making ectopic pregnancy the primary cause of maternal mortality during the first trimester of pregnancy. Known risk factors for ectopic pregnancy include pelvic inflammatory disease, prior tubal surgery, contraceptive history, and a history of infertility.[2] As the rise in incidence of ectopic pregnancy has paralleled the increase in cigarette smoking among women, it is reasonable to examine smoking as a potential risk factor.

Most of the evidence for the positive association of smoking and ectopic pregnancy derives from studies in which smoking was not a primary hypothesis (Odds Ratios = 1.5 to 3.9).[3–6] Recently Chow, *et al*,[7] investigated the potential etiologic relationship between cigarette smoking at the time of conception and ectopic pregnancy, considering the effect of age at initiation, smoking duration, and intensity on this event. An overall association of smoking with ectopic pregnancy was evident (OR = 2.2), but a dose-response was not demonstrated, possibly due to an inadequate number of cases. To permit more stable estimates of the risk of ectopic pregnancy by level of smoking, a case-control study using data from a large perinatal registry was conducted.

Methods

The University of Illinois Hospital (UIH) Perinatal Network collects information on 425 variables for all maternal and neonatal events occurring at its 12 member hospitals. Data are abstracted daily from medical records by trained abstracters and entered into the UIH perinatal database.

Women with an ectopic pregnancy (n = 701) presenting at UIH Perinatal Network Hospitals from 1983–87 were identified. Cases with a prior ectopic pregnancy were excluded (n = 67), leaving 634 total cases for study. Controls were a 5 percent random sample of all women without a prior history of ectopic pregnancy delivered of a single live-born infant (n = 4287) at these same hospitals. Women with pregnancies resulting in spontaneous abortions or fetal deaths were excluded for use as controls in this study because of the known relationship between maternal smoking and these reproductive outcomes.[8,9]

Cigarette smoking data in the UIH perinatal database is a measure of smoking during the current pregnancy. It is recorded as a dichotomous variable (yes/no) and as a continuous variable (number of cigarettes smoked per day). Ascertainment of smoking history was similar between cases and controls. Information on smoking as a dichotomous variable was available for 93.4 percent of the cases and for 91.9 percent of the controls; information on cigarette dose was available for 87.9 percent of the cases and 87.6 percent of the controls. Five levels of cigarette smoking were considered: nonsmokers; less than 10 cigarettes/day; 10–19/day; 20–29/day; and 30 or more/day.

Other variables collected on the perinatal abstract form were examined as potential risk factors: maternal age, race, payment method (as an indicator of socioeconomic status), gravidity, parity, prior spontaneous abortion, and prior induced abortion. Past or present pelvic inflammatory disease, past and current contraceptive use, and detailed fertility history were not available for this analysis.

The odds ratio and 95% Taylor series confidence intervals were used to describe the association between ectopic pregnancy and smoking.[10,11] Adjusted odds ratios were calculated using the Mantel-Haenszel technique and 95% confidence intervals according to the method of Robins, Greenland, and Breslow.[12] Tests for trend were computed by the Mantel extension.[13] To adjust simultaneously for multiple factors, a multiple logistic regression model was fitted with smoking as a dichotomous independent variable (yes/no) and ectopic pregnancy as the dependent variable.[14] The model was restricted to women with no prior history of spontaneous abortion since spontaneous abortion history modified the smoking-ectopic relationship.

An adjusted dose-response relationship between smoking and ectopic pregnancy was tested in a second multivariable model, with cigarette smoking treated as a continuous variable. In a third multivariable model, smoking was treated as a series of dummy variables to estimate dose-specific odds ratios.

Results

The rate of ectopic pregnancy at the University of Illinois Perinatal Network hospitals from 1983 to 1987 was 7.9 per 1000 live births. Increasing maternal age, Black race, increased gravidity, increased parity and prior spontaneous abortion are risk factors for ectopic pregnancy in this population (Table 1). Asians had a lower risk of ectopic pregnancy than other ethnic groups.

Women who reported smoking during pregnancy had a greater than twofold risk of ectopic pregnancy. Controlling for maternal age, race, payment method, gravidity, parity, and spontaneous abortion separately did not alter this crude estimate (range of estimates = 2.2–2.4). Smoking raised the risk of ectopic pregnancy less among women who had a prior spontaneous abortion (OR = 1.6, 95% CI = 1.1, 2.3) than among women who had not (OR = 2.5, 95% CI = 2.1, 3.1). This is due to the higher prevalence of smoking among women with ectopic pregnancy who have *not* had a prior spontaneous abortion (Table 1).

The smoking effect among women with no prior history of spontaneous abortion, adjusting for maternal age and race (Black versus other) was OR 2.5 (95% CI = 1.9, 3.2) (Table 2). A dose-gradient between cigarette smoking and ectopic pregnancy was evident when smoking was evaluated as a continuous variable (regression coefficient = 0.049, S.E. = 0.006) or as a categorical variable (Table 2 and Figure 1).

Discussion

In this study, women who reported smoking during pregnancy had a greater than twofold risk of ectopic pregnancy. This effect is similar to that seen in previous studies (Table 3).[4–7] The reported association is strengthened by the dose-response after adjusting for maternal age and race. Based on the estimates presented here, 60 percent of the ectopic pregnancies among smokers may be due to smoking.[11]

The significantly increased risk of ectopic pregnancy associated with increasing age and with Black race demonstrated in this report is consistent with other studies of ectopic pregnancy.[2] The gravidity and parity effect observed in the crude analysis disappeared when adjusting for prior spontaneous abortion. While in this population there was no increased risk of ectopic pregnancy associated with prior induced abortion, an increased risk with prior spontaneous abortion among multigravid women was observed. studies of the relationship between ectopic pregnancy and abortion of either type have been equivocal.[2,5,13–19*]

A major strength of this study is the large and ethnically diverse sample. Data collection was conducted without knowledge of the study's hypothesis, thereby preventing bias due to differential data collection for cases and controls. Despite the unexpected lower rate of ectopic pregnancy in this population, it is unlikely to affect the ascertainment of smoking data or the internal validity of the comparisons.

It is possible the exclusion of spontaneous abortions, antepartum and intrapartum fetal deaths in the control group led to an overestimate of the smoking effect since smoking increases the risk of spontaneous abortion and fetal deaths. A separate analysis including these outcomes in the control group did not alter the dose gradient observed.

The smoking data reported here refer to behavior during the current pregnancy as ascertained from medical records at the termination of pregnancy rather than interview or biochemical measures. For those identified as smoking during pregnancy, smoking behavior at conception and the duration of smoking prior to conception were unknown. Although these factors may be influential,[7] they seem unlikely to entirely explain the association with level of cigarette smoking. Additionally, women who stopped smoking just prior to pregnancy were not identifiable and their inclusion in the non-smoking group may lead to a conservative estimate of the relationship between smoking and ectopic pregnancy.

A weakness of this study is that three previously identified risk factors for ectopic pregnancy were not available in the University of Illinois Perinatal Network database and therefore could not be evaluated. These are prior or current contraceptive use, past or current history of pelvic inflammatory disease (PID), and past or current sexually transmitted diseases (STD). The World Health Organization's multinational study[6] of ectopic pregnancy found that adjustment for past history of PID or STD and for intrauterine device (IUD) use at the time of conception did not alter estimates of risk for current cigarette smokers when compared to pregnant (RR = 3.1) or nonpregnant (RR = 1.8) controls. Chow, *et al*, demonstrated an increased risk of tubal pregnancy associated with current smoking which was independent of past IUD use.

If the association between smoking and ectopic pregnancy is causal, the biologic mechanism might be one of several suggested by human and animal studies. In theory, any anatomic or physiologic factor impeding the transit of the ovum or blastocyst to the uterus may lead to an ectopic pregnancy.[20] Alterations in normal tubal architecture and tubo-ovarian relationships can mechanically delay ovum transport. This may explain the high incidence of ectopic pregnancy associated with tubal infection, pelvic surgery, and endometriosis which may cause partial tubal occlusions and/or pelvic adhesions.[21] However, up to 50 percent of the ectopic pregnancies are unexplained by any identifiable anatomical tubal factor.[22]

In humans, cigarette smoking can alter tubal motility by increasing muscular tone and the wave amplitude of tubal contractions as determined by uterotubal insufflation before and after smoking. Nicotine exposure leads to a short period of increased uterotubal activity followed by a longer period of tubal inactivity, providing increased opportunity for tubal implantation.[23]

Non-human primate and rodent studies have also demonstrated an alteration from baseline levels of tubal motility following injection of nicotine.[24–27] Nicotine treatment has been shown to delay ovum entry into the uterus, blastocyst formation, and blastocyst implantation as well as to alter spacing of implantation sites. These studies indicate cigarette smoking and nicotine are capable of affecting motility and could disrupt the complex sequence of coordinated tubal

*Holt V, Daling J, Voigt L: Induced abortion and the risk of subsequent ectopic pregnancy. Presented at the 21st Annual Meeting of the Society for Epidemiologic Research, Vancouver, Canada, June 1988.

contractions necessary for normal ovum transport.

Alternatively the effect of smoking on the occurrence of ectopic pregnancy may be due to the impairment of cellular and humoral immunity.[28–31] Smoking may be part of the causal chain linking pelvic inflammatory disease to ectopic pregnancy. It is possible that altered immunity in cigarette smokers may increase the incidence and prevalence of both tubal infection and pelvic inflammatory disease. However, the hypothesized association between smoking and pelvic inflammatory disease has not yet been explored.[7]

Basic research is needed to clarify the specific mechanism by which smoking may "cause" ectopic pregnancy. Epidemiologic studies controlling for all known risk factors are needed to confirm the dose-response relationship observed in this study between smoking and ectopic pregnancy.

ACKNOWLEDGMENTS

This research was supported by the Perinatal Network of the University of Illinois Hospital, Chicago, IL. The findings were reported in a paper presented at the American Public Health Association 116th Annual Meeting, Boston, MA, November 14, 1988.

National Maternal and Child Oral Health Workshop

A national workshop entitled "Maternal and Child Oral Health" will be held September 10–12, 1989 in Washington, DC. The Workshop will solicit expert scientific and policy opinion from invited participants concerning mechanisms to optimize oral health for the maternal and child population.

The purpose of the National Workshop is to provide a set of recommendations and health policy proposals to the US Public Health Service which, when implemented, will improve the oral health of mothers and children. A report of the final recommendations will be disseminated for use by agencies, organizations, health care providers, and the public.

Maternal Smoking during Pregnancy: No Association with Congenital Malformations in Missouri 1980–83

MICHAEL H. MALLOY, MD, MSc, JOEL C. KLEINMAN, PhD, JANICE M. BAKEWELL, WAYNE F. SCHRAMM, MA, AND GARLAND H. LAND, MPH

Abstract: Using a multisource birth defects registry developed by the Missouri Center for Health Statistics for the years 1980–83, we examined the relation between maternal smoking during pregnancy and the occurrence of congenital malformations. There were 288,067 live singleton births in this data set of which 10,223 had one or more congenital malformations. When adjusted for potential confounders the odds ratio for congenital malformations in the infants of women who smoked during pregnancy was not increased (odds ratio = 0.98, 95% confidence interval = 0.94 – 1.03). We examined the relation between smoking and groups of malformations using the International Classification of Diseases, 9th Revision, as well as analyzing for certain specific malformations within each group and found no increased risk for infants of smokers. (*Am J Public Health* 1989; 7[illegible]43–1246).

Introduction

Maternal cigarette smoking during pregnancy has been positively associated with low birthweight infants[1,2] and increased infant mortality.[3,4] The relation between smoking and the occurrence of congenital malformations is less certain. The biologic rationale for exploring the relation between smoking and congenital malformations is based on the results of experiments exposing animals to various teratogens that occur in cigarette smoke.[5–8] These teratogens include among others nicotine and cadmium which have been associated with cleft palate, anophthalmia, exencephaly, limb defects, and rib fusions.[7,8] Carbon monoxide, a major constituent of cigarette smoke has been associated with minor limb defects, but is considered more of an embryotoxic agent than a teratogen.[5,9] Clinical reports have suggested a higher prevalence of congenital heart disease in the infants of smokers[10] as well as a higher prevalence of oral clefts.[11] Other clinical reports have found no association between maternal smoking during pregnancy and congenital malformations.[12,13]

In order to examine the relation between maternal cigarette smoking and congenital malformations, we used a multisource birth defects file from Missouri. This file gives more complete ascertainment of birth defects than birth certificates alone and also contains information on maternal smoking during pregnancy.

Methods

The Missouri Birth Defects Registry for the years 1980 to 1983 is a linked file of birth certificates, hospital discharge diagnoses, neonatal intensive care unit diagnoses, Crippled Children Service diagnoses, and death certificates for children under two years of age. Linkage to the birth certificate was accomplished by matching last names and date of birth for death certificates, neonatal intensive care unit files, and Crippled Children Service files. Because names were not available on the hospital discharge file, matching was based on hospital of birth, date of birth, mother's zip code, and the child's sex and race. Match rates for the four files to the birth certificate approximated 90 percent.

This analysis was limited to singleton births. The total number of singleton births over the four-year period was 302,971. We excluded all records that were incomplete for the variables in our analysis. We were left with 288,067 records or 95 percent of the total singleton births. Variables used in this analysis and obtained from the birth certificate include race, the mother's martial status, educational attainment, age, and parity. Parity was defined as the number of live births plus abortions (induced and spontaneous) and stillbirths experienced by a woman. Information on the mother's smoking status during pregnancy was ascertained from the birth certificate as reported by the mother in terms of packs of cigarettes smoked per day. The categories recorded were nonsmoker, less than one pack per day, or one or more packs per day.

Malformations from this study were limited to those within the Version Nine - International Classification of Diseases (ICD-9) codes Congenital Malformation Chapter and to the ICD-9 Digestive System Chapter.[14] Malformations were analyzed as groups according to the 12 subchapters of the ICD-9 Congenital Malformation Chapter. These groupings attempt to categorize based on the anatomical relatedness of various specific defects (see Appendix). In addition, we analyzed several specific malformations that had been previously reported to be related to maternal smoking.

Multiple logistic regression was used to assess the effects of maternal smoking on congenital malformations, adjusting for maternal characteristics (age, marital status, educational attainment, and parity).[15] Separate models were fit for all malformations, for each group of malformations, and for each specific malformation. We ran separate models for Blacks and Whites for all malformations, groups of malformations, and specific malformations. The odds ratio for malformations for Black smokers, however, did not appear different from those of Whites.* The results presented thus combine both races with an adjustment for race within each model. Because parity had been observed to have significant interactions with maternal age in previous work done on infant mortality,[3] we fit models with two-way interactions between parity and maternal age. As in previous work, we also add a term to control for high parity (parity 3 or more for mothers under 25 years of age and parity 4 or more for those 25 or over).

Results

There were 10,223 infants (3.5 percent of live births) with one or more congenital malformations ascertained from the multisource file and 13,582 unique malformations (4.7 percent of live births). Only one-fifth of these were identified from the birth certificate portion of the file. The hospital discharge diagnosis file was the largest contributor of unique diagnoses, providing over 65 percent of them. The distribution of the number of malformations per infant was 79 percent with only one malformation, 14 percent with two malformations, and 7 percent with three or more malformations.

The prevalence of smoking and malformations by selected population characteristics is shown in Table 1. Blacks reported having smoked during pregnancy more than Whites, the women aged 18–19 years reported smoking more often than the women in the older aged strata, the least educated mothers reported smoking the most, single mothers smoked more than married mothers, and the high multiparity mothers had a higher prevalence of smoking than lower parity mothers.

The adjusted odds ratios (OR) for all malformations for smokers of less than a pack a day vs nonsmokers was 0.99 (95% confidence interval (CI) = 0.93, 1.04). For smokers of one or more packs per day vs nonsmokers, the OR = 0.98 (95% CI = 0.92, 1.05). Because no dose response relation was observed in this data set between the level of smoking and all malformations, we chose to report models with only two levels of smoking (nonsmokers vs smokers).** For certain specific malformations, however, we did examine for a dose response relation across the three levels of smoking and report these results in the text.

**Results of other models available on request to authors.

No congenital malformations occurred significantly more frequently in the infants of smokers than nonsmokers following adjustment for other maternal risk factors (Table 2). Only for gastrointestinal malformations did maternal smoking suggest a trend toward being a risk factor (OR = 1.11, 95% CI = 0.96, 1.29). Several congenital malformations, however, did appear to occur less frequently in infants of smokers. The odds ratio for malformations of the integument was less than 1.0 for smokers (OR = 0.82, 95% CI = 0.70, 0.97). The odds ratio for eye/ear/nose/throat malformations (OR = 0.84), ventricular septal defects (OR = 0.87), valvular defects (OR = 0.74) and cleft lip/cleft palate (OR = 0.84) suggested a lower prevalence in smokers although the 95% confidence intervals included 1.00.

We analyzed for several specific malformations within major organ systems that had been reported previously as being associated the maternal smoking during pregnancy. For example, the adjusted odds ratio for anencephaly for smokers compared with nonsmokers was 0.77 with a 95 percent CI of 0.44, 1.36. The odds ratio for atrial septal defects was 1.04 (95% CI = 0.70, 1.55).

The large number of odds ratios near 1.00 might suggest the data or methods used are not capable of detecting an effect of smoking. As an example of the validity of our model, we examined the odds ratio for chromosome malformations for various age groups. It is widely accepted that women over 35 years of age are at higher risk for having an infant with a chromosome abnormality. In fact, our data show the adjusted odds ratio for a chromosome malformation for women age 35 years and older was 7.04 (95% CI = 4.82, 10.28). There was no significant age-parity interaction for chromosome malformations ($p > 0.5$).

Discussion

The reported incidence of congenital anomalies varies from a low of 0.8 percent of live births[16] to a high of 7.1 percent.[17] This variation in the reported incidence of malformations makes it extremely difficult to determine the

TABLE 2—Adjusted Odds Ratios[a] for Congenital Malformations for Smokers Among Singleton Births to Missouri Residents by Congenital Malformation, 1980–83

[a]Odds ratios adjusted for maternal age, race, martial status, educational attainment and parity

validity of reports of associations between congenital malformations and potential risk factors. Because the Missouri Birth Defect File uses several sources of information to obtain diagnoses of malformations, we feel this file comes close to accurately assessing the number of malformations in a birth cohort. In addition, ascertainment of malformations is more complete because two files, the Crippled Children Services file and the death certificate file, include diagnoses made up to two years after birth. The Missouri Birth Defects Registry's completeness is similar to the Centers for Disease Control Birth Defects Monitoring Program.[18] For many birth defects, the Missouri system appears to be more complete. However, the Missouri system is not as complete as the more comprehensive Metropolitan Atlanta Congenital Defects Program.[18]

In our analysis we did not find a relation between maternal smoking during pregnancy and the occurrence of congenital malformations. These findings merit attention because of the large sample size available for this analysis and the opportunity to adjust for variables that may confound the relation between smoking and malformations. For example, the positive associations with smoking reported by Shiono, *et al*.[19] for ventral hernias (OR = 10.1), omphaloceles (OR = 3.0), and other gut abnormalities (OR = 12.6) are based upon five, five, and six cases, respectively. Shiono's results may well be based on the chance distribution of a larger number of cases among smokers.

Other studies where positive associations have been reported between maternal smoking and congenital malformations may suffer from problems of failure to adjust for potential confounding variables.[20,21] Evans, *et al*,[21] reported an unadjusted association between maternal smoking and anencephaly (relative risk = 1.76 for smokers of more than 20 cigarettes per day). When the relation was examined by socioeconomic status the dose response relation between smoking and anencephaly was not apparent in the lowest socioeconomic strata and was inconsistent in the upper strata. Both socioeconomic status and race have been reported to be associated with congenital malformations as well as smoking.[17,22,23]

Several reports have suggested a lower rate of malformations in infants of smokers.[19,24,25] We did observe one group of malformations (malformations of the integument) for which maternal smoking during pregnancy did seem marginally protective (OR = 0.82, 95% CI = 0.70, 0.97). This observation was also reported by Shiono, *et al*.[19] Hook, *et al*,[25] reported a lower risk of Down Syndrome in infants of smokers. We observed no protective relation between smoking and chromosomal abnormalities (OR = 0.99).

Our analysis of the relation between maternal smoking during pregnancy and the occurrence of congenital malformations does not support a causal role for smoking. The validity of this observation may be questioned on the basis of an under-ascertainment of smoking using birth certificate data attenuating the relation between malformations and smoking. However, the prevalence of smoking in the Missouri data is similar to that reported in other populations.[3] In addition, we have no reason to believe there was differential reporting of smoking between women who had infants with malformations and those who did not have malformed infants (especially since many of the malformations were identified from sources other than the birth certificate). Secondly, the validity of our analyses might be questioned on the grounds of lumping specific malformations into groups of malformations within organ systems. However, the analysis of many more specific malformations with many fewer cases results in lower statistical power to find a relation and greater chances of finding spurious relations. We did analyze for several specific malformations that others had found to be related to maternal smoking and found no relation (e.g., anencephaly, ventricular septal defects, atrial septal defects, valvular defects, clubfoot, and umbilical hernias). It is interesting to note that the lumping of specific malformations did not mask the risk associated with age for certain malformations, e.g., Down Syndrome, within the chromosome malformation group. Within our model for chromosomal anomalies we did confirm the marked increased risk associated with age over 35 years for both multiparous women and primiparous women (OR = 7.04). This observation may lend support to the validity of analyzing the data across groups of malformations.

The lack of relation between smoking during pregnancy and congenital malformations in liveborn infants may be partially a result of a selection bias. Because smokers have twice as many abortions as nonsmokers[26] and 30 percent more fetal deaths,[3] fetuses with malformations among smoking mothers may be underrepresented in a study of live births. Despite the lack of a relation between maternal smoking during pregnancy and the occurrence of malformations in liveborn infants, the established relation between smoking and infant mortality and morbidity[3,4,27] argues against maternal smoking during pregnancy.

Conference on Health and Social Services for Elderly, Disabled Announces Call for Abstracts

The Department of Social Security of Regione Emilia Romagna is organizing an international scientific meeting, to be held in Bologna, Italy from April 17–21, 1990, to address the systems and science related to health and social services for the elderly and the disabled.

The objective of the conference is to focus on the problems of planning, organizing, and managing health and social services for this population, utilizing a multidisciplinary approach to solving the complex problems. Conference participants will be drawn from various groups, including systems analysts and scientists, professional health care providers, and policy-makers so that the final program will emphasize the interactions of the various interests and disciplines.

Interested program participants may submit an abstract (maximum one page, typed) representing an individual presentation, or proposals for an entire session, with subject matter and individual speakers identified. The deadline for submitting abstracts and session proposals is December 15, 1989. Papers accepted by the Scientific Committee will be published in the conference proceedings.

Send abstracts and proposals to: Professor Pier Paolo Puliafito, Università di Genova, Viale Causa, 13, 16145 Genova, Italia. Telefax: 39-10-310086.

Does Maternal Employment Affect Breast-Feeding?

NATALIE KURINIJ, PHD, PATRICIA H. SHIONO, PHD, SANDI F. EZRINE, MS, AND GEORGE G. RHOADS, MD, MPH

Abstract: A prospective survey of maternal employment and breast-feeding initiation and duration was conducted among 668 Black and 511 White women who delivered their first child in Washington, DC. Ninety-one percent of White women (n = 511) and 80 percent of Black women (n = 668) reported working during pregnancy. Black women who planned to return to work part time vs full time were more likely to breast-feed rather than formula-feed (adjusted odds ratio, 2.3; 95% confidence intervals (CI) = 1.4, 3.7). Using Cox regression, Black women who returned to work had a shorter duration of breast-feeding than those not returning to work (hazard ratio = 0.5 (CI = 0.3, 0.9)). Black and White women returning to professional occupations had a longer duration of breast-feeding compared to women returning to sales or technical positions (hazard ratio for Black women = 2.4 (CI = 1.4, 4.4); hazard ratio for White women = 1.6 (CI = 1.0, 2.5)). In addition, White women in professional occupations had a longer duration of breast-feeding than women in clerical positions (hazard ratio = 1.7 (CI = 1.1, 2.6)). Until employers in the United States develop a maternity policy which does not discourage breast-feeding, the recommended six months of breast-feeding will be difficult to achieve for most employed women. (*Am J Public Health* 1989; 79:1247–1250).

Introduction

Participation of women with infants in the labor force has risen dramatically over the last 10 years. In 1977, 32 percent of women with a child under one year of age worked outside the home[1] By 1982, this proportion increased to 43 percent, and today the majority (52 percent) of women with infants are in the labor force.[1] While employment could adversely affect the initiation and continuance of breast-feeding, there is little evidence to document this relationship.

In this analysis, we examine the relation between maternal employment and the initiation and duration of breast-feeding separately among Black and White women. We assessed whether maternal employment during pregnancy and the intention to return to work affect a woman's decision to breast-feed, whether the duration of breast-feeding differs between women who return to work and those who do not, and the employment variables (occupation, timing of return to work, or hours worked) which are associated with duration of breast-feeding.

Methods

Healthy Black and White primiparae over 17 years of age who delivered a normal, singleton infant weighing more than 2200 grams were consecutively selected from the delivery logs at each of three metropolitan Washington, DC, hospitals. The study design and procedures have been described.[2] A total of 1,409 women were asked to participate in the study and 84 percent (n = 1,179) agreed. Women were interviewed in the hospital between February 1984 and March 1985. Information was obtained regarding maternal sociodemographic characteristics (age, education, marital status, and occupation during pregnancy), the timing of anticipated return to work, as well as whether this would be full-time or part-time work. Breast-feeders were defined as women who breast-fed at all regardless of formula supplementation (n = 755).

Address reprint requests to Natalie Kurinij, PhD, Collaborative Clinical Vision Research Branch, National Eye Institute, NIH, Building 31, Room 6A49, Bethesda, MD 20892. This work performed while author was at the Prevention Research Branch, National Institute of Child Health and Human Development. Dr. Shiono and Dr. Rhoads are with the Epidemiology Branch, Prevention Research Program, NICHD/NIH; Ms. Ezrine is with Survey Research Associates, Inc., Baltimore, MD. This paper, submitted to the Journal July 21, 1988, was revised and accepted for publication April 5, 1989.

Women who breast-fed in the hospital (n = 755) were subsequently interviewed in their homes at one, three, and seven months postpartum. Any women who indicated she had stopped breast-feeding at the one-month or three-month home interview was subsequently interviewed by telephone with a shortened interview schedule. Women still breast-feeding at seven months postpartum were contacted by phone at one year to determine their infant-feeding history. Thus, we have information on duration of breast-feeding from birth to one year postpartum and information on maternal employment from birth to 7 months postpartum.

Of the 755 women choosing to breast-feed, 36 who started school were deleted because there were too few for meaningful comparisons with employment. Follow-up interviews among the 718 women (306 Black, 412 White) provided information on whether a woman was still breast-feeding, and if not, when she had stopped, when a woman returned to work, the number of hours she worked and her current occupation.

The US Census Bureau categories were used to define occupation codes.[3] Managers, writers, lawyers, and registered nurses were the most frequent occupations in the professional category. The clerical group was comprised mostly of secretaries and stenographers. The service professions were primarily represented by private household occupations, and occupations providing food, health, or personal services. Sales persons were largely involved in the sale of personal goods and services, and technicians were mostly in fields other than health or science.

Analyses

Logistic regression was used to estimate the adjusted odds ratio for breast-feeding while controlling for sociodemographic and employment variables. Coefficients were estimated by the maximum likelihood method.[4] The Cox proportional hazards regression model[4] was used to determine the employment variables associated with breast-feeding duration after controlling for socioeconomic variables. Life-table analysis was used to graphically present the effect of occupation on duration of breast-feeding.[4]

Results

Initiation of Breast-feeding and Anticipated Return to Work

Eighty percent of Black women (n = 668) and 91 percent of White women (n = 511) reported working during pregnancy (Table 1). Black women worked primarily in clerical

occupations, White women in professional occupations. Women who worked in professional or technical occupations during pregnancy were more likely to breast-feed than women in other occupations or those not employed. Breast-feeding rates did not differ between women who anticipated a return to work in the first year and those who did not, with or without adjustment for the effects of maternal education, age, and marital status in a multivariate model.

Among the 560 Black women and 371 White women who stated they intended to return to work, 71 percent of Black women and 82 percent of White women did so by the fourth postpartum month. Among White women, breast-feeding rates were significantly lower among women planning a return to work in the first two months postpartum than among those planning a later return (Table 1). This effect was present to a lesser extent among Black women. Hours of planned work was not associated with breast-feeding rates in either ethnic group. However, a greater proportion of Black women (74 percent) compared to White women (61 percent) anticipated a return to full-time work (more than 24 hours a week).

Logistic regression analysis was conducted in each ethnic group to determine which employment variables affected choice of infant feeding method in hospital. After adjusting for maternal age, education, marital status, occupation, and planned timing of return to work; the only employment variable significantly associated with breast-feeding among Black women was a planned return to part-time vs full-time work, OR 2.3 (CI = 1.4, 3.7). In a similar analysis among White women, no maternal employment characteristic was significantly related to breast-feeding in the hospital.*

Duration of Breast-feeding and Maternal Return to Work

Women returning to professional occupations had a longer mean duration of breast-feeding than women in other occupations (Table 2). Among White women only, the later the return to work the longer the mean duration of breast-feeding. Mean duration also was longer for women returning to part-time rather than full-time work.

Cox proportional hazard regression analyses in each ethnic group are presented in Table 3 and were conducted to determine if a woman's return to work and the timing of this return influenced duration of breast-feeding. After adjustment for the effects of demographic variables and formula use in the hospital, the hazard ratio (HR) of 0.5 for Black women who did not return to work compared to Black women who return between five and seven months postpartum indicates that the former were twice as likely to continue breast-feeding as the latter.

Cox proportional hazard regression analyses were also conducted to examine the effect of employment variables on duration of breast-feeding among women who returned to work (Table 4). Black women who worked in sales or technical occupations and White women who worked in clerical occupations discontinued breast-feeding sooner than women in professional occupations (Table 4). In addition, White women in sales or technical occupations had a shorter duration than professionals, HR = 1.6 (CI = 1.0, 2.5). There was a trend toward a shorter breast-feeding duration for women who returned to work full-time rather than part-time.

Life-table analysis by maternal occupation is presented in Figure 1. Duration of breast-feeding was longest among women in professional occupations; one-half of them were still breast-feeding at 38 weeks postpartum. In the other occupational groups, one-half were still breast-feeding at 14 to 22 weeks. The effect of maternal occupation on duration of breast-feeding was, for the most part, similar in both ethnic groups.

Discussion

A 1981 national survey found that college-educated women, who did not work outside the home, were more likely to continue breast-feeding than those who were employed.[5] Another survey of a selected sample of primarily White, married women[6] found that the timing of a woman's return to work and the number of hours she worked were important determinants of weaning while specific occupation had little effect. With the exception of these two reports, there is little empirical data regarding the effect of employment on breast-feeding.

We previously examined the effects of maternal age, education, ethnicity, hospital of delivery, family income, marital status, and attendance in childbirth classes on the incidence of breast-feeding in this sample of women.[2] Initiation of breast-feeding was most strongly associated with increasing maternal education.[2] The odds ratio for breast-feeding increased from 2.6 (CI = 1.9, 3.7) for women with 13 to 16 years of education to 5.2 (CI = 2.7, 10.2) for those with greater than 17 years of education when compared to women

*Sample size is decreased from 232 in Black and 299 in White women due to missing data.

with a high school education or less. Ethnicity was also associated with the initiation of breast-feeding (OR for White vs Black = 2.0 (CI = 1.4, 3.1)).[2] Duration of breast-feeding was substantially shorter among Black as compared to White women.[2] In both ethnic groups, the use of formula supplements in hospital was associated with a shorter duration of breast-feeding.[2]

In this paper we examined the effect of employment on initiation and duration of breast-feeding. Black women who anticipated a return to work within the first postpartum year and intended this return to be part-time were twice as likely to breast-feed in the hospital as those planning to work full time. Among White women, neither the planned timing of return to work, planned hours of work, or occupation were related to breast-feeding in the hospital. The majority of Black women (63 percent) planned a return to full time work, and the breast-feeding rate was lowest in this group. The socioeconomic need to return to work in the early postpartum months on a full-time basis may be strong among Black

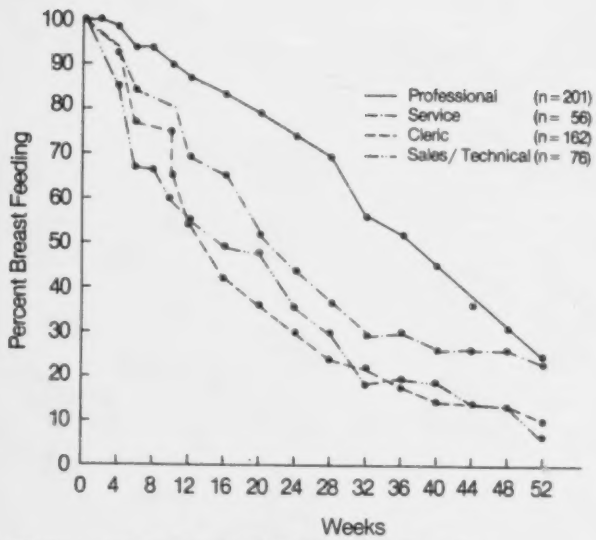

FIGURE 1—Duration of Breast-Feeding by Maternal Occupation.

women in this study who were largely single mothers. This need to return to full-time work may have had an adverse effect on the initiation of breast-feeding.

The effect of actual return to work was also different in the two ethnic groups. Black women who had not returned to work at seven months postpartum breast-fed longer than those returning to work earlier; there was, however, no difference between Black women returning to work early, e.g., at one or two months postpartum, and later, e.g., at six or seven months postpartum. Among White women, there was a positive trend between discontinuing breast-feeding and month of return to work; however, this trend was not statistically significant.

Occupation influenced duration of breast-feeding, and this association remained after adjustment for maternal sociodemographic characteristics. Women in professional occupations had a significantly longer duration of breast-feeding than women in sales or technical occupations. White women in professional occupations breast-fed longer than those in clerical occupations.

Because employers in the United States do not follow a general maternal leave policy, many working women by necessity resume employment during a time period that conflicts with the need for considerable mother-infant contact in breast-feeding. Expressing breast milk is possible but difficult in many work situations. The findings of this study emphasize that women employed as professionals, appear to have control over their work environment and can structure a more satisfactory relationship between the demands of employment and infant feeding. On the other hand, women employed in clerical and sales occupations appear to have little freedom to accommodate the demands of employment and the needs of their infants. Breast-feeding for six months postpartum is a recommended goal[7] which is difficult to meet for most employed women and particularly difficult for those employed in non-professional occupations. This finding emphasizes the need for the development and implementation of a maternal leave policy, particularly for women who choose to breast-feed.

AACC Press Seeking Information on Rare Tests

AACC Press, the publishing arm of the American Association for Clinical Chemistry, is actively seeking new listings for the 1990/91 edition of the *Directory of Rare Analyses* (DORA). The directory, currently in its third edition, is a vital reference tool for physicians and others seeking analyses not commonly performed in hospital or reference laboratories. The directory contains detailed listings of these uncommon tests, along with the address and contact person for the laboratory performing the test.

The editors, Jocelyn M. Hicks, PhD, Children's Hospital National Medical Center, and Donald S. Young, MB, PhD, University of Pennsylvania, are currently soliciting new submissions for DORA '90/91. The *deadline* for test submissions is October 31, 1989.

For inclusion in DORA '90/91, a test must *NOT* be performed by two or more of the large reference laboratories. Individuals who know of a laboratory performing an unusual test, or wish to submit a test that their laboratory offers, should contact Tina Edwards, AACC Press, 2029 K Street, NW, Suite 700, Washington, DC 20006. Tel: 202/857-9717 • Toll Free 800/892-1400 • FAX 202/887-5093.

Pregnancy Characteristics and Outcomes of Cambodian Refugees

PETER GANN, MD, MS, LUAN NGHIEM, BS, AND STANLEY WARNER, MD

Abstract: This study describes the perinatal characteristics of Cambodian refugees in Massachusetts. Data were abstracted from the records of 452 consecutive pregnancies among Cambodian women and 110 low-income Whites receiving obstetrical services at the same clinic and hospital in Lowell, Massachusetts. Pregnancies of Cambodian women were marked by a higher proportion of older mothers, grand multiparas, previous adverse birth outcomes, and short interpregnancy intervals. We identified maternal anemia (29.9 percent with hemoglobin <110 g/L) and inadequate utilization of prenatal care (32.3 percent with first visit in the 3rd trimester) as possible risk factors for the Cambodians. The prevalence of primary cesarean birth was only 6.3 percent in the Cambodians, compared to 15.6 percent in the comparison group, largely due to the infrequent occurrence of prolonged labor among multiparas. Despite the prominence of several risk factors for adverse birth outcomes in this population, major pregnancy complications were less common and the prevalence of low birthweight (6.4 percent) was close to the state average. Logistic regression analysis of risk factors for low birthweight identified young maternal age and short stature as the strongest factors operative in this community. Many of our findings are consistent with a strong cultural emphasis on managing the size of the baby to avoid a difficult labor and delivery. (*Am J Public Health* 1989; 79:1251–1257.)

Introduction

Since 1981, refugees from Cambodia have become a growing part of the flow of immigrants from Southeast Asia to the United States. These refugees are primarily rural people who are marked by the experience of having survived mass exterminations in Cambodia in the late 1970s and the harsh conditions of relocation camps in Thailand.[1] Not surprisingly, the emphasis in this refugee community on the replenishment of their population with healthy children is reflected in a high birth rate.[2] The maintenance of a cohesive culture with markedly different attitudes toward pregnancy and childbearing could provide insights into the complex relation between cultural beliefs, poverty, and pregnancy outcome.

This paper describes a survey of pregnancy characteristics and outcomes among Cambodian refugees in Lowell, a small city in northeastern Massachusetts. Lowell has a total population of 97,000 that now includes approximately 16,000 Cambodian refugees. An additional 7,000 were expected to arrive during 1988, attracted by entry-level jobs in the electronics and service industries and an established base of family networks and cultural organizations. Although the rate of employment among these refugees is relatively high, low salaries and educational levels as well as crowded living quarters are serious problems. According to data compiled by the US Centers for Disease Control, the prevalence of low birthweight in two of the largest relocation camps in Thailand was at least 20 percent.[3] Three published studies, which included relatively small numbers of Cambodian pregnancies, suggested that Cambodians had less favorable birth outcomes than other Southeast Asian groups such as the Hmong and Vietnamese.[2,4,5] A study of mental health problems among all Indochinese refugees concluded that Cambodian women, particularly the many who had lost spouses, had the highest risk for serious psychiatric impairment.[6] We initially assumed that current living conditions—in addition to the trauma and deprivation of the past, history of poor pregnancy outcomes, and the difficulty of relocating to a strange culture—would put the Cambodians at risk during pregnancy and childbirth in the US.

The purpose of this study was to define the prevalence of adverse birth outcomes and to describe the major risk factors in this large population. In addition, we contrasted the pregnancy characteristics of this relatively unique racial/ethnic group with those of White, native-English speaking women of low income in Lowell and in Massachusetts as a whole.

Methods

Lowell General Hospital (LGH) is the only hospital in Lowell that provides Cambodian interpreters for prenatal patients and is currently the only hospital in Lowell providing obstetrical care for Medicaid patients. Therefore, nearly all Cambodian women in Lowell who receive prenatal care will at one time or another during pregnancy become registered at LGH. Birth lists and a log of patients registered in the prenatal clinic were reviewed to select all Cambodian women receiving prenatal care at LGH between January 1, 1981 and July 30, 1987. Women transferred for care or delivery at another hospital, women who left the area during pregnancy, home births and stillbirths were recorded in the prenatal clinic log. Attempts were made to trace each of these women and obtain the obstetrical records. Only two women, who moved out of the area before delivery, could not be traced. A total of 449 pregnancies (444 singleton pregnancies) among 310 women were found. The number of pregnancies increased from 12 in 1981 in 119 in the first seven months of 1987.

A trained investigator reviewed the medical chart for each Cambodian pregnancy using a coding manual to abstract detailed information on 53 variables concerning the patient's demographic and medical features; none of these variables were missing for more than 3 percent of the eligible subjects. Identical information was obtained from the records of 110 comparison pregnancies that were registered at the same clinic immediately after every fourth Cambodian pregnancy. These patients, who represent the majority at the clinic, were Caucasian women (often of Greek, Irish, Italian, or French-Canadian ancestry) whose primary language is English. As in the Cambodian group, 90 percent of these patients were

registered for Medicaid. For some variables, comparison data were also available for White or non-Asian women participating in the statewide Maternal and Infant Care (MIC) Program providing services for low-income women.[7] This group is 40 percent White, 27 percent Black, and 33 percent Hispanic. Comparison groups were selected to delineate contrasts due to cultural or genetic factors rather than socioeconomic ones.

We defined low birthweight as a birthweight less than 2500 grams and premature delivery as gestational age less than 37 weeks. Adequacy of prenatal care was determined using an established index developed by the Institute of Medicine.[8] Details of this index and other key definitions—such as gestational age, rate of maternal weight gain, labor times and inter-pregnancy interval—are provided in the Appendix. Confidence intervals (95%) were calculated using normal approximation or exact methods as appropriate. Crude and stratified odds ratios were calculated to estimate the magnitude of association between risk factors and outcomes. A microcomputer program specifically designed for logistic regression was used for multivariate analyses.[9]

Results

The prevalence of selected major maternal risk factors existing *prior* to pregnancy is shown in Table 1. There are fewer teenage mothers and primiparas, and more older mothers and grand multiparas than in the comparison group; nearly one-fourth of the Cambodian mothers were under 60 inches in height; a greater proportion had experienced previous adverse birth outcomes; and over one-fourth became pregnant six months or less after their previous delivery.

Table 2 shows the risk factors observed during pregnancy. Although the mean weekly weight gain was slightly less among the Cambodians, there was very little difference in the proportion of women experiencing sharply reduced rates of weight gain. On the other hand, the Cambodians were far less likely to experience high rates of weight gain (more than 1.5 lbs/week). Anemia, as determined by hemoglobin concentration, was more common among the Cambodian women. Cigarette smoking and regular alcohol consumption were far more common in the clinic comparison population. There was a small difference between the groups in prenatal care, but both Lowell populations were considerably worse in this regard than the statewide MIC population, in which only 14.3 percent received "inadequate" prenatal care.

Labor and delivery results are shown in Table 3. The major finding is the much lower prevalence of primary cesarean birth among the Cambodians, almost entirely attributable to a difference between the multiparous women. Prolonged first stage of labor and a clinical diagnosis of dystocia, the leading reason for primary cesarean section, were more common among multiparas in the comparison group. We detected a small increase in the occurrence of very short second stages of labor among the Cambodians, but the prevalence of potential precipitous labor was higher than expected in both groups.

The prevalence of adverse outcomes among groups in the study is shown in Table 4. The prevalence of low birthweight was lower in the Cambodians than the clinic comparison or statewide MIC women. The difference between Cambodians and the clinic group held for both primiparas and multiparas. The data in Table 4 and Figure 1 indicate that the frequency distribution for birthweight was narrower and slightly shifted to the left for the Cambodians compared to the clinic group. There were fewer stillbirths in the Cambodian population and premature birth was approximately equally common among all three groups. Comparison of gestational age distributions in Figure 2 reveals that the Cambodian women have a relative deficit of babies born after 40 weeks of gestation and an excess of babies born at marginally premature or early gestational ages from 35 to 39 weeks.

Table 5 presents the crude odds ratios for low birthweight and prematurity in the Cambodian population alone, considering several variables of interest. Although the effect estimates are not highly precise, there are some clear differences between the effect of certain variables on low birthweight versus premature birth. In particular, height, age less than 20, and nulliparity appeared to be more predictive of low birthweight than prematurity. Age less than 20 was in fact inversely associated with premature delivery. Slow maternal weight gain (less than 0.5 lbs/week) showed a relatively strong association with delivery of an underweight infant, a relationship that proved to be unconfounded by maternal stature.

Table 6 presents the results of a logistic regression analysis of the risk factors for low birthweight among the Cambodians. More saturated models gave similar point

TABLE 4—Prevalence of Adverse Birth Outcomes in Cambodian Refugee and Clinic Control Groups

Birth Outcomes	Cambodian Refugees	Clinic Controls	MIC, 1980–84
Low birthweight			All non-Asians: 9.1% (8.5, 9.7) White:
<2500 gms	6.4% (4.1, 8.6)	10.3% (4.6, 16.0)	7.3% (6.5, 8.1)
Primiparas	9.4%	12.7%	—
Multiparas	4.6%	7.7%	—
Mean birthweight	3146 gms	3326 gms	All non-Asians: 3215 gms White: 3291 gms
Birthweight 2500–3000 gms	28.3% (24.1 32.5)	15.9% (9.0, 22.8)	All non-Asians: 18.8% (18.0, 19.6)
Stillbirths	2 (0.4%)	3 (2.7%)	All non-Asians: 30 (0.7%)
Premature birth	9.1% (6.4, 11.8)	6.4% (1.8, 11.0)	All non-Asians: 8.2% (7.6, 8.7)

estimates for the effect of individual variables. Age less than 20 and maternal height less than 60 inches were the only substantial risk factors in the multivariate analysis. Adjusted odds ratios were generally similar to the crude odds ratios. Slow maternal weight gain was a strong independent predictor of low birthweight but was excluded from the multivariate

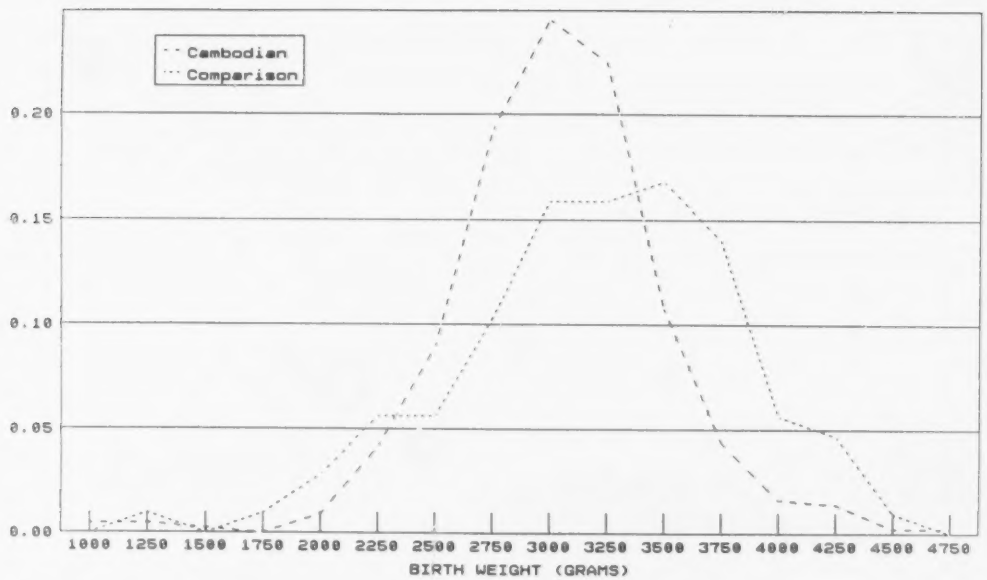

FIGURE 1—Relative Frequency of Birth Weights among Cambodian Refugees and Clinic Comparison Group

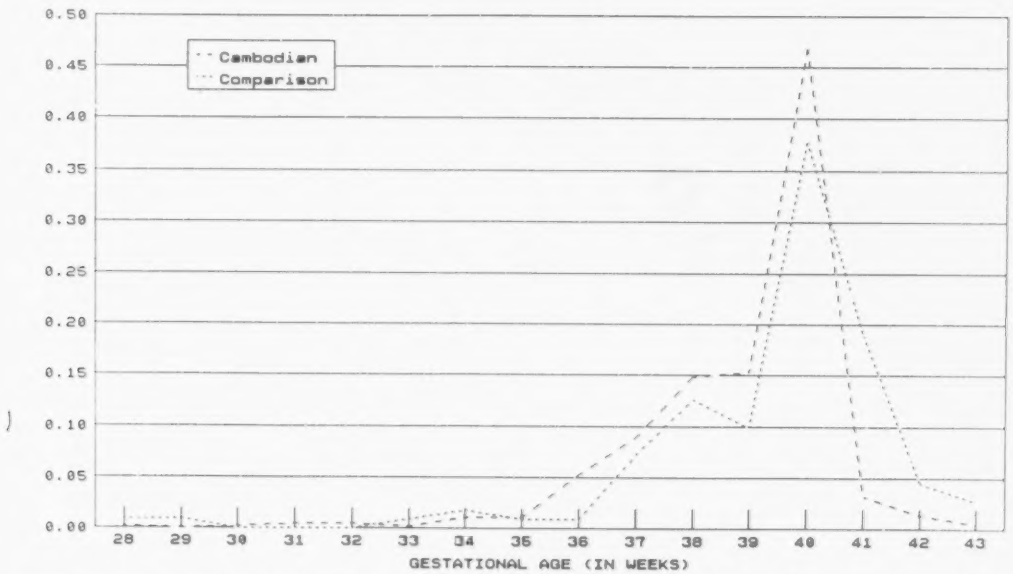

FIGURE 2—Relative Frequency of Gestational Ages among Cambodian Refugees and Clinic Comparison Group

models since it could be considered in part a manifestation of rather than a risk factor for a pregnancy impaired by intrauterine growth retardation.

Discussion

Contrary to our expectations prior to this study, the Cambodian refugees had more favorable birth outcomes than White low-income women in Lowell and low-income women in Massachusetts in general. The prevalence of low birthweight (LBW) infants, stillbirths, major pregnancy complications, and primary cesarean delivery were all lower in the Cambodian population. The prevalence of LBW was in fact similar to that of all non-MIC women in Massachusetts, which averaged 5.8 percent between 1980 and 1984. The prevalence of LBW among the refugees changed little during the interval from 1981 to 1987; it was 6.5 percent during 1981–84 and 6.2 percent during 1985–87. Some of the differences in the birthweight distribution between the refugee and other populations is attributable to more births taking place after 37–40 weeks gestation among the Cambodians. Jarvis and co-workers obtained a strikingly similar result when comparing birthweight and gestational age patterns of Indian and Pakistani immigrants to Whites in London.[10] The asso-

*Odds ratios for the major predictor variables were not significantly altered by inclusion of other independent variables in the model (see text).

ciation between low pre-pregnancy weight and slightly shorter gestation provides one possible explanation for such similar results with diverse Asian groups.[11]

Examination of the risk profile for the Cambodian women reveals several sharp contrasts to the other groups. Risk factors more common among the Cambodians (older mother, grand multiparity, previous small infants or infant deaths, short interpregnancy interval, inadequate prenatal care, and anemia) appear to have been offset at least in part by a low prevalence of teenage primiparous mothers and low rates of smoking and alcohol use. Muecke found similar contrasts in a comparison of Southeast Asian to non-Asian pregnancies in Seattle.[12] It is encouraging to note that the conditions leading to previous poor outcomes in this population, such as malnutrition or infection in the relocation camps, have not had an irreversible effect on pregnancy outcome in the US.

Short maternal stature was one of two major predictors of low birthweight in this population. Hardy and Mellits, using data from the Collaborative Perinatal Project, have shown that prevalence of LBW defined as 2500 grams or less begins to rise as maternal stature falls below about 63 inches.[13] It is reasonable to assume that many of the LBW infants born to these small women are physiologically sound, and probably reflect genetic tendencies toward small body size. Therefore, clinically significant LBW among these refugees might be overestimated in the present study. Previous investigators have pointed out the existence of ethnic variation in "normal" birthweights and the need for racially appropriate definitions of low birthweight based upon follow-up of morbidity and mortality during the first year of life.[14–17]

These data indicate that about one-third of the Cambodian refugee women enter prenatal care during the third trimester and about 35 percent receive inadequate prenatal care as determined by the timing and quantity of visits. This problem is also seen in the White patients from the same clinic, in comparison to low-income women statewide. Despite use of the hospital by a large number of Cambodians and the availability of interpreters on a limited basis, the Cambodians tend to view the hospital with some fear and/or mistrust during pregnancy. We found no evidence for any alternative, non-Western systems of prenatal service in the community, although it does appear that some Cambodian women have their pregnancy diagnosed relatively early during a single visit to one of the Vietnamese physicians in the community. We were able to analyze the use of prenatal care for succeeding pregnancies in Lowell and found that there was a slight tendency toward later prenatal registration with each succeeding pregnancy. Although we would not de-emphasize prenatal care for this group, we found, as others have in different populations, that the quantitative adequacy of prenatal care by itself was not an important factor in pregnancy outcome.[18]

Anemia is another problem that, although more frequent among the Cambodians, did not appear to have a substantial effect on birth outcome. Future studies will provide a more detailed analysis of the hematologic conditions in this population. Attention must be focused on possible dietary iron deficiency as well as chronic intestinal blood loss from parasitic infestation and hereditary hemoglobin disorders, which have been reported among Cambodian refugees by other investigators. Hemoglobin disorders that are likely to be found in this population include Hemoglobin E, and both alpha and beta varieties of thalassemia.[19] In a survey that included newly arrived Cambodian refugees, Catanzaro and Moser reported that 67 percent of the Cambodians had positive stools for intestinal parasites and that the presence of hookworm was associated with anemia.[20]

Previous investigators have postulated that Southeast Asian women have lower hematocrit and hemoglobin values during pregnancy due to physiologic adjustments having no clinical significance.[21] This could arise from greater expansion of plasma volume, for instance. This explanation appears to be consistent with our data showing no relation of anemia to birthweight until hemoglobin drops below 100 grams/L. Despite some relevant data from animal studies, the long-term effect of anemia during pregnancy on the child, particularly in regard to cerebral development, is not yet well understood.[22] The refugee's prenatal diet could be high enough in calories to avoid LBW, yet borderline in specific nutrients such as total iron, protein, and calcium.

Short interpregnancy interval was extremely common among the Cambodians. The number of LBW infants was too small to permit a reasonably precise, unconfounded estimate of the effect of interval on birthweight. However, we found no relation between short intervals and anemia or slow maternal weight gain in the second pregnancy. As pointed out by Klebanoff, interpregnancy interval could be more important in populations where maternal nutrition may not be adequate.[23]

The finding of a strong negative association between age under 20 and premature delivery is not typical in the general population and suggests that the LBW found among the Cambodian teenagers was specifically due to intrauterine growth retardation. The reasons for the apparent protection of teen mothers from premature delivery are not clear. Since teenage pregnancy may become more common among the Cambodians, the current low prevalence of LBW could begin to increase. The life experience and cultural practices of the

refugees under age 20, who came of age either in relocation camps or in the US, might differ considerably from that of the older women. So far, we have found no evidence for a trend toward an increase in smoking or alcohol use among the Cambodian teens. In fact, the few smoking women in our study tended to be older than the non-smokers.

Although the Cambodian women are small and tend to have small pelvic sizes, they had a lower frequency of labor complications and prolonged labor, resulting in a very low rate for primary cesarean delivery. The tendency for the Cambodians to have smaller babies, after shorter gestation, would explain at least part of this difference. We and others working with Southeast Asian refugees found a strong belief in the importance of limiting the size of the infant in order to avoid a difficult labor, but we found no evidence for any specific intervention by the mothers to achieve this other than some restriction of food intake during pregnancy. The fear of cesarean section seems quite reasonable given the risks of surgical delivery in rural Cambodian and the possible stigmatization of the cesarean newborn for religious or cultural reasons.

Among the strengths of the present study are the large size of the Cambodian population studied and the inclusion of virtually all pregnancies since 1981 in this population. In addition, the provision of nearly all obstetrical services by a single hospital resulted in a fairly uniform level of health care service. The study was limited by the surprisingly small number of low birthweight (LBW) outcomes and the absence of an LBW definition specific for this racial/ethnic group.

In summary, we found that the Cambodian refugees possess an unusual risk profile for adverse birth outcomes. Birth outcomes themselves were good in comparison to other groups of low-income women, leading us to conclude that previous poor outcomes in refugee camps were due to reversible conditions. Studies presently underway will determine whether these relatively good birth outcomes among Cambodian refugees in Massachusetts are complemented by lower rates of infant mortality. To an unknown extent, the outcomes observed in this group of women who survived the periods of extermination and relocation might also have been favorably influenced by the selection out of the reproducing population of women with chronic illnesses. Indeed, we found that relatively few of these women began pregnancy with major chronic diseases. Although strong additional interventions to improve basic outcomes may not be urgently needed, the problems of teen pregnancy, resistance to prenatal care, and the possible long-range effects of maternal anemia deserve particular attention in this community.

APPENDIX
Definitions

Gestational age: the final, best estimate of pregnancy duration based upon the last menstrual period, maternal examination, ultrasound, and clinical examination of the newborn.

First stage of labor: the interval from the onset of regular, painful contractions to the full dilatation of the cervix.

Second stage of labor: the interval from full dilatation to delivery of the infant.

Interpregnancy interval: the interval from the previous birth to the last menstrual period prior to the current pregnancy.

Rate of maternal weight gain: Since many of the women did not know their pre-pregnancy weight, it was often impossible to determine the total weight gain during pregnancy. Instead, the rate of maternal weight gain during pregnancy was estimated by dividing the weight obtained on the two most widely spaced clinic visits by the number of intervening weeks. This measure of average weekly weight gain is reasonable since the largest portion of the sigmoidal curve for weight gain during pregnancy is linear and observations could be discarded if the two weight measurements were too late or too close in time. We chose to discard values obtained for intervals less than four weeks or within six weeks of the due date.

	Gestation (weeks)	Number of Visits
Adequate[a]	22–25	4 or more
	26–29	5 or more
	30–31	6 or more
	32–33	7 or more
	34–35	8 or more
	36 or more	9 or more
Inadequate[b]	22–29	1 or less
	30–31	2 or less
	32–33	3 or less
	34 or more	4 or less
Intermediate	All combinations not specified above.	

[a]First prenatal visit must also be in the first 13 weeks of pregnancy.
[b]First prenatal visit after 28th week is automatically inadequate.

Adequacy of prenatal care index: This index (first published in reference 8) is as follows:

ACKNOWLEDGMENTS

New Curriculum Available to Upgrade Drug Abuse Counseling Skills

The National Institute on Drug Abuse has developed a new instructional training resource for employee assistance program (EAP) professionals and others who need to update or increase their knowledge and skills for responding to drug-using employees in the workplace.

Single copies of the document, entitled *Drug Abuse Curriculum for Employee Assistance Program Professionals*, are available free on request. It was developed in response to increasing concerns about the effects of drug abuse in the workplace and the need for EAP staff to be prepared to help employees with problems resulting from the abuse of a wide range of drugs. Several experts in the field—in consultation with NIDA and a national panel representing academic institutions, unions, businesses, EAP practitioners, professional associations, and the public sector—authored the modules of the *Curriculum*. The six modules include:

- Organizational Implications of Drug Abuse Programming: Making the Organization Work for You (by Dr. Sheila Akabas and Meredith Hanson);
- Supervisor Training (by Dr. Bradley Googins);
- Case Management (by Dr. Muriel Gray);
- Assessment (by Dr. Dale Masi);
- Overview of Drug Abuse and Employee Assistance Programs at the Workplace (by Dr. Judith Vicary); and
- Pharmacology of Abused Drugs (by Dr. George Woody).

The *Curriculum* covers the topics of overall manifestations of drug abuse in the workplace; pharmacology; the physical, psychological, and behavioral effects of drugs—both licit and illicit; the relationship of drug abuse to job performance and other workplace issues; the role of the EAP in drug abuse assessment and case management; supervisor training; and organizational responses.

The adaptability of the *Curriculum* allows for its use in both continuing education (CE) and in-service training programs offered through academic institutions and has been designed so that continuing education credits may be offered to participants. Pennsylvania State University has adopted the *Curriculum* for use in their CE Statewide Chemical Dependency Counseling Treatment Program which serves over 300 students annually. Other university-based CE programs are currently examining the *Curriculum* for potential adoption as a course text.

Single copies of *Drug Abuse Curriculum for Employee Assistance Program Professionals* are available free upon request from the National Clearinghouse for Alcohol and Drug Information, P.O. Box 2345, Rockville, MD 20852. Tel: 301/468-2600.

Comments or questions regarding the *Curriculum* should be directed to Jim Lipari, Chief, Employee Assistance Program Section, Workplace Policy Research Branch, Division of Applied Research, NIDA, Rockville, MD 20857. Tel: 301/443-0802.

Catholicism and Fertility in Puerto Rico

JOAN M. HEROLD, PHD, CHARLES F. WESTOFF, PHD, CHARLES W. WARREN, PHD, AND JUDITH SELTZER, MPH

Abstract: This paper examines the association between fertility and religious affiliation among Puerto Ricans. Bongaarts' proximate determinants framework is used to compare religious categories on behaviors that directly affect fertility. We found no difference in recent fertility between Catholics and non-Catholics in Puerto Rico (total fertility rate = 2.5). We also found Catholics and non-Catholics to be similar on age at first marriage (23.3 and 23.4 years, respectively), contraceptive use (71 percent and 69 percent of married women currently contracepting), and breast-feeding practices (mean duration of breast-feeding of 4.4 and 4.3 months). Differences were observed between less committed and more committed Catholics in total fertility rate, age at first marriage, and contraceptive use, but these differences were not large and were in the opposite direction from the expected. Our findings support the theory of convergence of Catholic and non-Catholic fertility for the US. Our discrepancy with findings from the National Survey of Family Growth is evidence of the cultural diversity in the US Hispanic population and indicates the importance of disaggregating by ethnicity or national origin when studying this population. (*Am J Public Health* 1989; 79:1258–1262.)

Introduction

There has been extensive study of the differences in Catholic and non-Catholic fertility in the United States over the past 30 years.[1–7] Early studies in the US found Catholics had higher fertility and lower contraceptive use than non-Catholics.[1,2] Later research presents two contrasting views. Some studies suggest Catholic and non-Catholic fertility behavior has converged to the point that the differential is negligible.[4] Other studies suggest Catholics continue to have distinctive fertility behavior relative to non-Catholics.[5–8] Most recently, Mosher, *et al*, have attributed the distinctiveness to the high fertility of Hispanic Catholics, such that when Hispanics were excluded from their analysis, Catholic and non-Catholic fertility in the United States converged. Among Hispanics, however, they observed an effect of religion, with Catholics having higher fertility than non-Catholics.[7] The analysis by Mosher, *et al*, however, is limited by the small sample of Hispanics in the National Survey of Family Growth and consequently an inability to disaggregate the Hispanic population into specific ethnic groups. Given the increasing numerical importance of the Hispanic population in the United States, if we are to draw definitive conclusions regarding Catholic and non-Catholic fertility in this country, we need studies that look at the Hispanic population controling for national origin.

Puerto Ricans are an important component of the US Hispanic population. Since Puerto Rico has commonwealth status with the United States, Puerto Ricans are United States citizens and have unrestricted travel to the mainland. They comprise the second largest Hispanic ethnic group residing in the United States, and their mobility is characterized by circular migration between Puerto Rico and the United States mainland. Because of the fluidity of movement between the island and the mainland, one can expect certain similarities between Puerto Ricans living in these two geographically distinct areas. Hence an analysis of the relation between Catholicism and fertility in Puerto Rico should have a direct bearing on this relation for Puerto Ricans living in the United States.

Our study will focus on both direct and indirect determinants of fertility in Puerto Rico, a framework of fertility analysis first introduced by Davis and Blake[9] and more recently modeled by Bongaarts.[10–12] Davis and Blake suggested that social, economic, and cultural factors (i.e., indirect determinants) operate through intermediate fertility variables (i.e., direct determinants) to affect fertility. Bongaarts, in modeling Davis and Blake's scheme, reduced the original set of 11 variables to four proximate direct determinants of fertility (nuptiality, contraceptive use, lactation, and abortion). Variations in the importance of the proximate determinants can either: account for group fertility differences, or explain how groups with similar fertility levels reached equality. In this paper, we use indicators for three proximate determinants (or intermediate variables) to examine the impact of religion on fertility in Puerto Rico. The central issue addressed is whether fertility differs by religious affiliation and/or religious participation in Puerto Rico. A further issue asks whether analysis of the intermediate fertility variables helps clarify the impact of religion on fertility in Puerto Rico. Two primary comparisons are made: 1) Catholic versus non-Catholic; 2) for Catholics the more committed versus the less committed.

Methods

The Sample

In 1982, the Puerto Rico School of Public Health and the Puerto Rico Department of Health, with technical assistance from the Division of Reproductive Health, Centers for Disease Control, conducted an island-wide assessment of fertility and family planning in Puerto Rico.

A two-stage, disproportionate stratified cluster sample design was used to select 4,500 households throughout the island of Puerto Rico. All women of ages 15–49 in each survey household were interviewed. A total of 3,175 women completed personal interviews, resulting in a completion rate of 91 percent. The data have been weighted to take into account: nonresponse at both the household and individual levels, and poststratification adjustments for age by residence, based on the age by residence distributions from the 1980 census of Puerto Rico and population estimates for Puerto Rico in 1982.

The analysis presented in this paper uses weighted data. However, only unweighted Ns are shown in the tables.

Variables

A two-question sequence was used to define religion and religious commitment. (The complete version of these questions in Spanish and English are presented in the Appendix.)

The data set contains only four categories for religious affiliation—Catholic, Protestant, Other, and None. In this study, non-Catholics are treated as one group because of the small proportions in each of the three non-Catholic categories (Protestant = 16 percent, Other = 9 percent, and None = 7 percent).

As suggested by Mosher *et al*,[7] religious participation is measured by church attendance. Catholics who attended services once a month or more were categorized as frequent attenders or more committed Catholics and those who attended services less than once a month were defined as infrequent attenders or less committed Catholics. As a check on this indicator, analyses were also done using communion participation as a measure of religious commitment. Results using the latter variable paralleled those for church attendance but are not shown.

Based on the above considerations, four groups were classified: Catholics (2,144) and non-Catholics (1,031); and for Catholics, the more committed (1,204) and the less committed (940).

Two measures of fertility are used: 1) mean number of children ever born; and 2) total fertility rate, defined as the average total number of births a woman would have if she were to pass through her reproductive lifetime experiencing the age-specific fertility rates of a given time period. The total fertility rate for this analysis was computed using the cohort-period technique.[13]

Of the four proximate determinants of fertility described by Bongaarts (marriage, contraception, lactation, and abortion), this analysis addresses the first three. Abortion data are not included in this study because reliable estimates of abortion prevalence are not available. The relation between the proximate determinants and fertility are explained in detail in Bongaarts[10,11] and Bongaarts and Potter.[12]

Results

In the aggregate, the mean number of children ever born is the same for Catholics, regardless of commitment level, and non-Catholics (Table 1). When we look only at women aged 40–49 years, a small difference exists between Catholics and non-Catholics, suggesting that there may have been a mild effect of religion on childbearing at an earlier point in time regardless of commitment.

TABLE 1—Mean Number of Children Ever Born and Total Fertility Rate* by Religion and Religious Commitment, among Women 15 to 49 Years of Age, Puerto Rico, 1982

				Catholics	
	Total	Catholic	Non-Catholic	More Committed	Less Committed
Mean Number of Children Ever Born	1.8	1.8	1.8	1.8	1.9
No. of Cases	(3175)	(2144)	(1031)	(1204)	(940)
Mean Number of Children Ever Born to Women Ages 40–49	3.5	3.6	3.3	3.6	3.5
No. of Cases	(698)	(474)	(224)	(281)	(193)
Total Fertility Rate	2.5	2.5	2.5	2.2	2.8

* Calculated for the 5-year period prior to the survey, using cohort-period method.

The current total fertility rate is 2.5 for both Catholics and non-Catholics. Among Catholics, however, those who are more committed to their religion appear to have lower fertility than the less committed Catholics (2.2 vs 2.8), a finding the opposite of that expected.

Marriage/Nuptiality

The mean age at first marriage (Table 2) is essentially equal for Catholics and non-Catholics. This equality is also revealed in percent ever married by age, where little difference is observed between Catholics and non-Catholics. Among Catholics, however, religious commitment raises the age at marriage from 23.3 to 24.4 years compared to the low of 21.9 years for less committed Catholics. The difference in nuptiality between more committed and less committed Catholics is concentrated in the younger ages, with more committed Catholic women under the age of 30 showing 10 to 20 percentage points fewer marriages than less committed Catholics at the same ages.

Contraception

Current contraceptive use is essentially similar for Catholics and non-Catholics both in terms of overall levels and methods used (Table 3). Female sterilization is the most prevalent method used by both groups (39.6 and 39.8 percent). When religious commitment is considered, more committed Catholics show a higher total level of contraceptive use as well as higher method-specific rates for most of the methods compared to less committed Catholics.

When future birth intentions are taken into account (Tables 4 and 5), differences again are minimal. For women who have completed childbearing (Table 4), the total contraceptive prevalence as well as the method mix is very similar for Catholics and non-Catholics, with female sterilization by far the most prevalent method (around 57 percent). There also is little variation in contraceptive use between more and less committed members of the Catholic faith. The largest differences for women who intend to have no more children are observed in the sex-specific sterilization frequencies, with committed Catholic women having higher male sterilization (8.2 percent) and less committed Catholics having higher female sterilization (60.6 percent).

In Table 5, those women using contraception to space their births show only slight group differences, the most pronounced being a slightly greater preference for the pill among Catholic women compared to non-Catholics, with more committed Catholics less likely to use the pill and more likely to use the IUD, condom, and rhythm than less committed Catholics; all differences are small.

Breast-feeding

Breast-feeding differences are again minimal. The highest percentage of ever breast-feeding (33.2 percent) is among the less committed Catholics; the lowest is among non-Catholics (30.7 percent). Mean duration of breast-feeding is 4.4 months, varying from 4.8 months among less committed Catholics to 4.0 months among the more committed Catholics.

Discussion

Our results indicate that recent fertility of Catholics and non-Catholics in Puerto Rico is virtually identical and the

importance of the proximate determinants through which women control their fertility is similar for Catholics and non-Catholics. Although we were unable to measure abortion, the similarity in levels of the three other proximate determinants and in total fertility, according to the Bongaarts model, implies little or no difference in abortion incidence across Catholic and non-Catholic categories.

Differences were observed between less committed and more committed Catholics in total fertility rate, age at first marriage, and contraceptive use, but these differences were not large and were in the opposite direction from the expected.

The finding of no effect of religious affiliation on fertility is consistent with earlier studies conducted in Puerto Rico. In a 1946 study, King claimed that although the Catholic Church had an intransigent position against all forms of contracep-

tion, it did not appear that the Church was an important deterrent to the use of contraception by Puerto Ricans.[14,15] Ten years later, Stycos, *et al*,[16] discovered that despite over 80 percent of Puerto Ricans classifying themselves as Catholics, attitudes and behaviors were predominantly favorable to the small family achieved by the use of birth control.

Our findings also fit with results of another recent study that reveals widespread adoption of contraception among the Puerto Rican population. In particular, variables that would suggest different social environments, such as socioeconomic status or urban/rural residence, were found to have little or no effect on contraceptive use in this population.[17] It is very likely that the small geographic area of the island may produce homogeneity with respect to contraceptive knowledge and contribute to broad accessibility of contraceptive techniques.

On the other hand, socioeconomic status has been observed to be associated with marriage patterns in this population, with more highly educated women marrying at later ages than less educated women.[18] However, as the Catholic and non-Catholic groups in our study have similar distributions of educational level, it is unlikely that controlling this variable would have affected our analysis.

An important implication of the findings in this study is that Catholicism is not an obstacle to effective contraceptive use among Puerto Ricans. Thus, public health workers in family planning on the island of Puerto Rico and on the US mainland need not be unnecessarily distracted by the role of Catholicism in the adoption of effective contraception among Puerto Ricans and can focus their efforts on other family planning issues of concern to the Puerto Rican community.

What bearing does our study have on the Catholic fertility debate in the United States? First, the total fertility rate (TFR) of 2.5 in Puerto Rico in 1982 is higher by 0.7 child than in the United States (TFR = 1.8 in 1982).[7] Since over two-thirds of Puerto Ricans are Catholic, their migration to the United States would contribute to a higher aggregate fertility rate for Catholics compared to non-Catholics. In such a case, however, fertility differences would be the result of differences in the ethnic composition of Catholics and non-Catholics and not the result of religion *per se*.

Our findings support the *convergence* argument because we show no difference in the fertility behavior of Puerto Rican Catholics and non-Catholics. Our results are not consistent with the finding of Mosher, *et al*,[7] that fertility was higher for Catholic Hispanics than for non-Catholic Hispanics in the United States. The primary explanation for this discrepancy is that the effect of religion on fertility may differ by ethnicity among Hispanics. Puerto Ricans comprise a much smaller proportion of the US Hispanic population than Mexican Americans, who make up 60 percent of the Hispanic population and have substantially higher fertility than Puerto Ricans.[19,20] If Catholics have higher fertility than non-Catholics among Mexican Americans, this would affect the relation between religion and fertility for the total Hispanic population. Our discrepancy with the findings of Mosher, *et al*, point to the importance of disaggregated research on the Hispanic population if we are to resolve the debate over the effect of Catholicism on fertility in the United States.

APPENDIX

Religion

1.5 ¿ Es usted católica, protestante, de alguna otra religión, o no pertenece a ninguna religión?

1__ Católica
2__ Protestante
3__ Otro, especifique _____
4__ Ninguna

1.7 ¿ Cuán frecuentemente asiste usted a servicios religiosos?

1__ Nunca
2__ Una vez al año o menos
3__ Varias veces al año
4__ Una vez al mes
5__ Dos o tres veces al mes
6__ Una vez por semana
7__ Más de una vez por semana

Nurse Midwifery Tuition Grant at University of Pennsylvania

The University of Pennsylvania Graduate Program in Nurse Midwifery has been awarded a grant from the US Department of Health and Human Services, Bureau of Maternal and Child Health and Resources Development, which provides tuition funds for a limited number of nurse midwifery trainees. Minimum criteria for application require a bachelor of science in nursing degree, leadership qualities, and a commitment to work in Title V or other publicly funded maternity care programs after graduation.

The deadline for completed applications is January 31, 1990. Applications for this graduate program can be obtained from:

Acculturation and Low Birthweight among Latinos in the Hispanic HANES

RICHARD SCRIBNER, MD, MPH, AND JAMES H. DWYER, PHD

Abstract: Self reports from 1,645 Latino mothers of Mexican descent who participated in the Hispanic Health and Nutrition Examination Survey (HHANES) were used to relate the birthweight of their infants to the HHANES acculturation index. After controlling for parity, a one point increase on the acculturation scale was found to be associated with a 1.19 (95% CI = 1.05, 1.34) increase in risk of maternal low birthweight (LBW) (1.98 risk increase for four points). The estimated relative risk increased to 1.34 (1.12, 1.60) with controls for age at interview, wealth, city size, and years of education; controlling for current smoking status reduced the relative risk to 1.31. US-born respondents were also at increased risk relative to Mexican-born, but this relation was explained by acculturation. The effect of education was found to depend on level of acculturation. Years of education was unrelated to risk among the Mexican-oriented, while increased education was associated with reduced risk in the US-oriented. These results suggest that factors associated with a Mexican cultural orientation may be protective against the risk of LBW. (*Am J Public Health* 1989; 79:1263–1267.)

Introduction

Concern about the relatively high rate of infant mortality in the United States has focused attention on the epidemiology of low birthweight (LBW), the major predictor of mortality in the first year of life.[1] In this regard, Latinos of Mexican descent present a surprising pattern. On the one hand they have one of the highest birthweight-specific fetal and neonatal mortality rates for LBW births of any ethnic group in the United States.[2] This finding is consistent with their status as a medically underserved minority,[3] and it may reflect a lack of medical intervention in the perinatal period.[4,5] On the other hand, the infant mortality rate for Latinos of Mexican descent is comparable to other Whites and is half that of Blacks.[6] This paradox has been explained by recent data on the distribution of LBW among Latinos.[2,6] Latinos of Mexican descent have one of the lowest risks of LBW births of any racial or ethnic group on which data are available. Thus, data on the prenatal experience of Latinos of Mexican descent may be informative concerning the conditions under which certain social and demographic risk factors lead to increased risk of LBW and infant mortality.[2]

In addition to a more favorable birth experience among Latinos relative to other US ethnicities and minorities, recent studies have indicated that nativity status (country of birth) of California Latino mothers is associated with the distribution of infant birthweights within the Latino population.[2] Furthermore, this association favors those mothers born in Mexico even though they are generally of lower socioeconomic status than those born in the United States.[6] This pattern of findings may be explained by at least two models: 1) Latino mothers who migrate are healthier than those who do not migrate; 2) birth in Mexico is merely a marker for a lifestyle that is protective against negative social influences on pregnancy outcomes. The purpose of this study is to explore the consistency of these competing explanations with data on Latino mothers from the Hispanic Health and Nutrition Examination Survey (HHANES).

Methods

The HHANES was conducted by the National Center for Health Statistics during 1982–84.[7] Three separate Latino populations (Cuban, Mexican, and Puerto Rican) within the United States were sampled. Data for the current study came from the Mexican respondents included in the Medical History portion of the HHANES.

The degree to which respondents have taken on the social and cultural characteristics of either a Mexican or US orientation was assessed using an index of acculturation. The index consisted of eight variables selected from an index of 21 variables developed by Cuellar in 1980 for Mexican Americans.[8] These eight variables were measured by 18 survey items concerned with various aspects of acculturation. Four of the acculturation variables measure language preference, three measure ethnic identification, and one measures nativity status. The first seven variables were scored from 1 (Mexican-orientation) to 5 (US-orientation); the nativity variable ranged from 1 (respondent and parents born in Mexico) to 4 (respondent nor parents born in Mexico). The acculturation score is the arithmetic mean of the scores for the eight variables (i.e., total score/8). The resulting scale ranges from 1.0 (Mexican-orientation) to 4.9 (US-orientation). For purposes of the current study, this index was also disaggregated into a seven-item non-nativity acculturation index (ranging from 1.0 to 4.9) and a nativity index (ranging from 1 to 4).

The mother's status with regard to an LBW birth was assessed from three questionnaire items:
1) "What is the total number of live births you have had?"
2) "Did the (only) child weigh less than 5 1/2 pounds (2,500 grams) at birth?"
3) "How many of your children (who were born alive) weighed less than 5 1/2 pounds (2,500 grams) at birth?"

Female respondents were classified as mothers if they indicated one or more live births in the first item. A mother was then classified as a LBW mother if she indicated one or more LBW births in either of the latter two questions (no = 0, yes = 1).

Smoking status was determined from the questions: "Do you currently smoke cigarettes?" Level of education was measured by reported years of education. Wealth index was measured by the ratio of average household income for the past 12 months over the poverty threshold income for 1982. Scores of less than 100 were below the poverty level for 1982. City size was an ordinal variable with 8 categories ranging from 1 (cities over 1,000,000) to 8 (towns less than 10,000).

The data were analyzed using logistic regression because the dependent variable was dichotomous. The model used was the following:[9]

$$\ln(\text{odds}[\text{Maternal LBW}]) = \alpha\ P1 + \beta_1\ P2 \ldots + \beta_x\ ACC + \beta_{x+1}\ AGEI$$

Where maternal LBW, parity of one (P1) and parity of two (P2) are dichotomous variables, and acculturation score (ACC) and age at interview (AGEI) are continuous variables. The CATMOD procedure in the software package SAS was used to analyze the data. Survey weights were incorporated by dividing each individual weight by the mean survey weight of all the Latino mothers analyzed yielding an average sample weight of one. Design effects were not incorporated in the analysis. The degrees of freedom for estimating the design effects in Hispanic HANES are small and therefore yield unstable point estimates. Test statistics generated using unstable point estimates of the variance could be misleading. However, the use of logistic regression for the analysis causes the design effect to converge on 1.0. In addition, including variables related to survey design (e.g. age, sex) also causes the design effect to converge on 1.0.*

Results

Total births ranged from one to 15. Mothers were eliminated from the analysis if data were unavailable on total births, acculturation index, or number of LBW births. One mother reported 11 births of which 11 were LBW births. The next highest number of reported LBW births was 4. The mother with 11 low birthweight births was 58 years old, born in the US, had an acculturation score of 2.0, and a survey weight above the average. She was the only case deleted from the analysis.

The 1,645 mothers reported a total of 6,216 births. Of these births, 299 were reported as LBW births. The overall proportion of LBW infants (4.8 percent) was comparable to the proportion of LBW infants for Mexican-Americans found by Williams[2] (4.7 percent) and Ventura[6] (5.3 percent) in cross-sectional analyses of California state and national vital records, respectively, in 1981. The percentage of LBW infants among Mexican born respondents in the HHANES (3.9 percent) was also comparable with that found by Williams (4.2 percent), as were the proportions of LBW infants among United States born respondents (5.5 percent) when compared with Williams (5.2 percent). However, the proportions of LBW infants among US-born (6.3 percent) and Mexican-born (5.0 percent) mothers reported by Ventura were higher than those found both by Williams and in the HHANES.

The distribution of the mothers on the acculturation index was bi-modal which may reflect the presence of two fairly distinct subpopulations of Latinos of Mexican descent (Figure 1). To explore the characteristics of these two subgroups defined by this distribution the mothers were dichotomized, those equal to or below an acculturation score of 2.4 were designated as Mexican-oriented and those above 2.4 designated as US-oriented (Figure 1). Demographically, Mexican-oriented mothers had a higher mean parity and lower means for years of education and income. Behaviorally, Mexican-oriented mothers were less likely to report current smoking of cigarettes (Table 1).

*Personal communication with Lester Curtain of the National Center for Health Statistics.

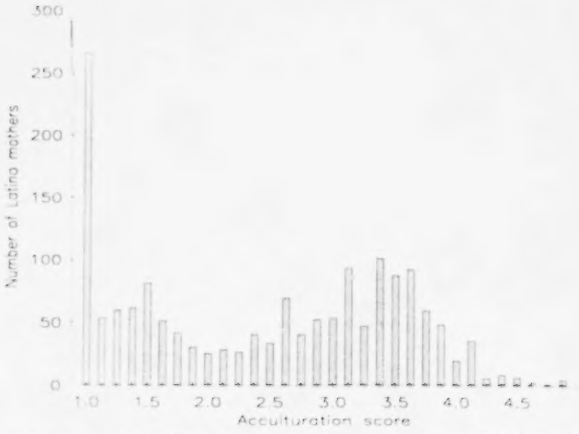

FIGURE 1—Distribution of all Latino Mothers in Hispanic HANES by Acculturation Score (n = 1.645)

TABLE 1—Variable Means by Cultural Orientation

Demographic/ Behavioral Variables	Mexican-Orientation			US-Orientation		
	n	Mean	S.D.	n	Mean	S.D.
Years of education	731	6.05	3.82	914	10.27	3.29
Wealth index (<100 poverty)	661	138.8	96.6	840	191.5	135.6
Age (years) at interview	731	42.1	14.3	914	38.5	14.0
City size (1 = urban, 8 = rural)	680	3.75	2.24	824	5.22	2.35
Parity (# live births)	731	4.24	2.95	914	3.41	2.44
Mexican-born (0 = no, 1 = yes)	731	.735	.447	914	.130	.334
Current Smoker (0 = no, 1 = yes)	731	.194	.396	914	.281	.450

The percentage of LBW mothers in the survey was 13 percent (11 percent among the Mexican-oriented women, 14 percent among US-oriented women). Mexican-oriented women were at lower risk of maternal LBW status within all parity groups except after primiparity (Figure 2).

When LBW status of mothers was logistically regressed on the acculturation score the coefficient for acculturation was positive ($\hat{\beta}$ = .080, S.E. = .067) but close to zero (Table 2). When parity was added to the model, the acculturation coefficient increased in magnitude ($\hat{\beta}$ = .172, S.E. = .071), reflecting the tendency of greater parity among Mexican-oriented women to mask the relation between LBW risk and acculturation. The regression coefficients for demographic variables (education, wealth index, age at interview, and city size) were all near zero with parity controlled.** However, current smoking status had a strong positive effect ($\hat{\beta}$ = .355 S.E. = .160) and remained so ($\hat{\beta}$ = .396, S.E. = .168) with controls for acculturation score. Notably, the positive effect of acculturation score on maternal LBW status was reduced ($\hat{\beta}$ = .157, S.E. = .071) after controlling for current smoking status (Table 2).

Education was the only variable that had a substantial

**Data available on request to author.

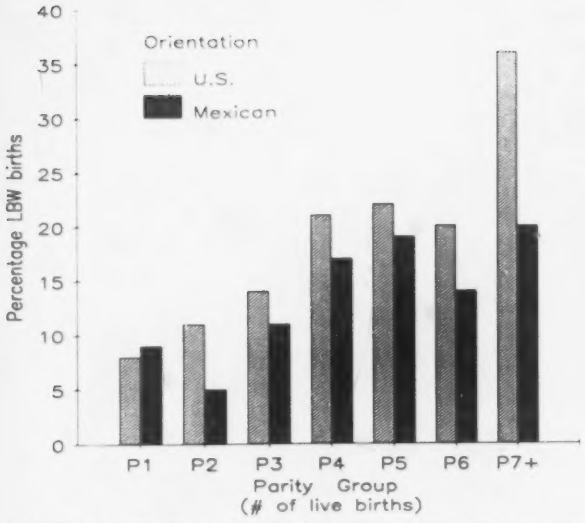

FIGURE 2—Percentage of Mothers with Low Birthweight Births for each Cultural Orientation by Parity Group

interaction with acculturation (Table 3). The interaction effect was negative ($\hat{\beta}$ = −.063, S.E. = .021) as was the main effect of education ($\hat{\beta}$ = −.069, S.E. = .026) while the main effect of acculturation ($\hat{\beta}$ = .234, S.E. = .081) was positive. This indicates that the effect of years of education on maternal LBW status varies with acculturation status. Specifically, years of education has no effect on maternal LBW status for Mexican-oriented women but a negative effect among US-oriented women (Figure 3).

To explore the independent effect of nativity, this component of the acculturation index was removed and maternal LBW status was logistically regressed on nativity and parity. The effect of nativity on risk was positive ($\hat{\beta}$ = .116, S.E. = .055), and increased ($\hat{\beta}$ = .158, S.E. = .068) with controls for demographic variables. The acculturation index with the nativity variable removed (i.e., a non-nativity based acculturation index) was also positive and substantial both controlling for parity ($\hat{\beta}$ = .196, S.E. = .082) and controlling for parity and the other demographic variables ($\hat{\beta}$ = .311, S.E. = .113). When both the nativity variable and the non-nativity acculturation variable were included in the analysis the effect of nativity was reduced to near zero ($\hat{\beta}$ = .030, S.E. = .089) while non-nativity acculturation status remained correlated with maternal LBW status ($\hat{\beta}$ = .160, S.E. = .132). This relation was more pronounced when demographic and behavioral variables were added to the model. The effect for nativity remained small ($\hat{\beta}$ = .043, S.E. = .100) while the effect for non-nativity based acculturation increased ($\hat{\beta}$ = .259, S.E. = .165) (Table 4).

For ease of interpretation and additional assurance that the results are not the result of model specification all independent variables were dichotomized and reentered into the regression equation. The model including acculturation score and parity indicated that the risk of maternal LBW among US-oriented Latinos was 1.64 times that of the Mexican-oriented mothers. This relative risk increased to 1.86 when all covariates were included in the model.

Discussion

This study confirms the previously reported reduced risk of LBW among the Latino mothers born in Mexico relative to Latino mothers of Mexican-descent born in the United States.[2,6] However, this association was weaker than that between measured acculturation and maternal LBW risk, and became negligible when the non-nativity acculturation variable was included in the regression model.

The self-reporting of pregnancy outcome involves recall error. The recall period in the HHANES is as long as 50 years, and no queries were made concerning whether or not an accurate birthweight was supplied to the mother at the time of delivery. As a result, overestimating birthweight by Mexican-oriented women could account for these results. However, a similar reporting bias was felt to be responsible for the low perinatal mortality rates for Latino infants of Mexican-descent when the data from linked birth and death certificates first became available.[11,12] It was subsequently shown by Williams in California that these low rates could not be the result of a systematic bias from underreporting by Mexican mothers.[2] It is therefore noteworthy that in the HHANES the proportion of mothers' self-reports of low birthweight, both overall and among the Mexican- and US-born subgroups, were not substantially different than that

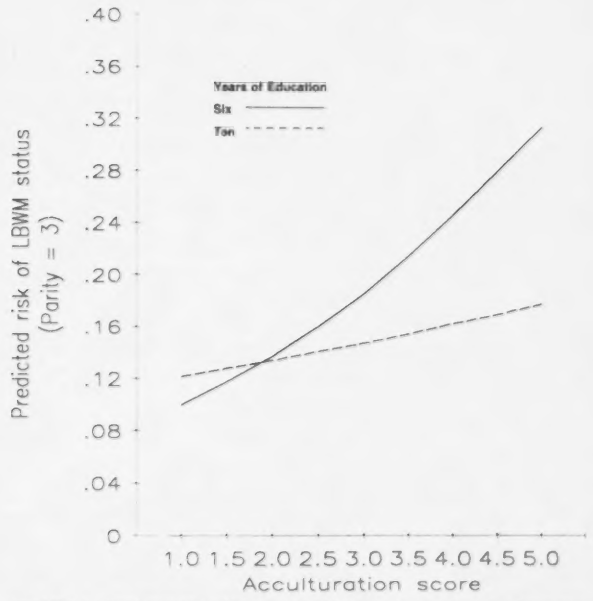

FIGURE 3—Predicted Risk of Maternal LBW Status by Acculturation Score and Years of Formal Education Demonstrating the Interaction of Acculturation and Education
Model: ln (Odds{Maternal LBW}) = $\alpha + \beta_1*(P3) + \beta_2*(ACC-3) + \beta_3*(EDUC-8) + \beta_4*((ACC-3)*(EDUC-8))$

found by Williams in California. Furthermore, numerous studies have found that birthweight is recalled with a high level of accuracy by mothers many years after the birth.[13–16]

Controlling for demographic risk factors in the regression model did not change the magnitude of effect of acculturation on maternal LBW status, in fact the effect became stronger. It may be that acculturation status acts as a marker for certain values, beliefs or lifestyles which protect these women from negative birth outcomes associated with the demographic pattern they possess.[2] Where formal education has little effect on maternal LBW status in Mexican-oriented mothers, it is negatively associated with maternal LBW status in US-oriented mothers. This observation is consistent with previous studies.[6,17] A study of infant mortality in Israel found that level of formal education in an out-group was directly related to infant mortality contrasted with the inverse relationship in the general population.[18]

Behaviorally, Latinos of Mexican descent demonstrate better nutrition, fewer premarital births, lower rates of smoking and alcohol use, and higher regard for parental roles when compared to other Whites.[2,19–22] Consistent with such findings, a higher proportion of the US-oriented Latino mothers responded that they currently smoked. Cigarette smoking was the only independent variable other than parity that has a strong effect on maternal LBW status both before and after controls for acculturation were added to the model. The effect of acculturation status, on the other hand, was reduced slightly by controlling for current smoking status, a behavior associated with the US orientation. The fact that the designation is an assessment of smoking status at the time of survey and not an indication of prenatal smoking probably

attenuates the association. Also, since no other behavior variables were controlled in the analysis, current smoker status could be a marker of a group of behaviors related to smoking and positively associated with maternal LBW status. This situation would exaggerate the apparent effect of this variable in the analysis.

Lack of prenatal care is often cited as a risk factor for LBW. However, Mexican-born Latinos have a lower rate of LBW than their US-born counterparts despite the fact they are more likely to receive late or no prenatal care.[6] These findings, together with those reported here suggest that Mexican-orientation is associated with behaviors or lifestyle predating pregnancy which are more important determinants of LBW than prenatal care. Thus utilization of prenatal care services among Latinos of Mexican descent may be associated with a lifestyle that places them at risk of LBW. Utilization of prenatal care may become more likely with the loss of Mexican values and beliefs which are protective against LBW.

These analyses demonstrate that Latinos of Mexican descent are not a homogeneous group with regard to risk for LBW. Furthermore, Mexican cultural orientation acts as a marker for a lifestyle which is associated with a favorable prenatal experience among these Latino mothers. Such an effect is seen primarily in the highly Mexican-oriented Latinos and lost when one moves away from this cultural orientation. It is noteworthy that conventional demographic risk factors for LBW, such as formal U.S. education, only become important for Latinos of Mexican descent as they move away from the Mexican orientation. This may be due to the lack of influence of these factors in the social environment that developed the culture which gave rise to the values and beliefs making up the Mexican orientation.

The components of the Mexican orientation which may provide protection are important from a prevention standpoint. Especially in light of the observation that this orientation may ameliorate the impact of demographic risk factors. Some possible components of the Mexican orientation that need further investigation include nutrition, familial integration, smoking and alcohol use, and out-of-wedlock births. How Latinos lose those attributes which proscribe adverse health behaviors and/or how they develop attributes which do not effectively proscribe them may be critical to our understanding of LBW.

Fetal Death Ratios in a Prospective Study Compared to State Fetal Death Certificate Reporting

MARILYN K. GOLDHABER, MPH

Abstract: A cohort of 6,254 pregnancies surviving at least 20 weeks of gestation was identified through pregnancy testing and follow-up at three Kaiser Permanente medical offices in northern California in 1981–82. Fetal death ratios per 1,000 live births were 12.1 for all fetal deaths versus 5.0 for the subset of fetal deaths reported to the California state registrar Only fetal deaths resulting in overnight hospitalization of the mother were reported. Seventy-nine percent of fetal deaths over 28 completed weeks since the last menstrual period (LMP) were reported versus only 10 percent between 20 and 28 completed weeks since the LMP. Ninety-three percent of fetuses over 400 grams were reported. The unreported fetal deaths were mainly those perceived by attending physicians as spontaneous abortion, especially missed or incomplete spontaneous abortion. Physicians apparently preferred the label of spontaneous abortion over stillbirth or fetal death whenever fetal maturity could not be substantiated, regardless of prior estimates of the date of the LMP. Fetuses as large and developed as potentially viable infants were the most likely to be reported. (*Am J Public Health* 1989; 79: 1268–1270.)

Introduction

State fetal death certificate reporting has been the primary source for determining the risk of stillbirth, or late fetal death, in the United States for more than 60 years.[1] While the legal definition of reportable fetal death has varied somewhat by time and state, reasonably consistent trends in fetal death ratios (the number of fetal deaths per 1,000 live births) have been observed across the country and over the years. Nevertheless, underreporting of fetal deaths is a well-recognized and pervasive problem[2–4] whose magnitude is unknown.

Most states now require that a fetal death certificate be filed for spontaneous fetal deaths over 20 weeks of gestation. Eight states also require filing certificates for earlier fetal deaths, and four states specify fetal delivery weight over 350–500 grams as an alternative reporting criterion to 20 weeks gestational age.* As recently demonstrated by Harter, *et al*,[4] and others in the past,[2,3] states with reporting requirements based on gestational ages less than 20 weeks or based on fetal delivery weight have consistently higher ascertainment of fetal deaths between 20 and 28 weeks. After 28 weeks of gestation, reporting of fetal deaths appears to be fairly complete.

Harter, *et al*, imply that reasons for underreporting may be related to the condition of the fetus upon expulsion. If it is macerated, malformed, or very small, its chances of being reported are diminished. If the fetus dies in utero before 20 weeks of gestation but is carried for days or even weeks afterward, as in the case of "missed abortion," whether or not it should be reported may be unclear to physicians.

The same medical personnel responsible for reporting fetal deaths often use the International Classification of Disease (ICD) index to code hospital discharge summaries. A late fetal death (ICD-9 code 656.4) is defined in the ICD-9 Tabular List as having more than 22 completed weeks of gestation while spontaneous abortion appears with a separate code (634) presumably for earlier fetal deaths occurring prior to 22 weeks. This may also cause confusion.

In California, Section 10175 of the California Health and Safety Code, first prepared in 1955, states, "Each fetal death in which the fetus has advanced to or beyond the twentieth week of uterogestation shall be registered." An advisory was later circulated to county health departments in 1978 stating that if the gestational age cannot be determined, a weight of over 400 grams and a crown-heel length of over 28 centimeters may be used as alternative reporting criteria. While this advisory is still in effect, existing copies are difficult to find. I was unable to locate written documentation from the state vital registration office, the county offices, or Kaiser hospitals.

To see which fetal deaths are likely to be reported and which are not, I used data from the Kaiser Permanente Medical Care Program in northern California collected for a large prospective study of pregnancy outcome. In this study there were 75 fetal deaths of 20 or more weeks of gestation within a cohort of 6,254 pregnancies surviving at least 20 completed weeks from the last menstrual period (LMP). Gestation was counted from the first day of the LMP until expulsion from the womb. Days 0–6 constitute the 0th week so that days 140–146 constitute the 20th week (this convention was established in prior prospective studies of pregnancy outcome).[5–8]

Methods

The Kaiser program in northern California is one of the oldest health maintenance organizations in the country, now providing prepaid medical coverage to about 2 million members. Ninety percent of the membership join through employee organizations and 10 percent as individuals. Kaiser members tend to report early for medical care, including pregnancy diagnosis; they also tend to stay with the program for long periods of time.

In early 1983, researchers attempted to identify all women having positive pregnancy tests or pregnancy confirmation at three Kaiser clinics in the south San Francisco Bay Area, September 15, 1981 through June 30, 1982. The purpose was to establish a cohort of women in early stages of pregnancy during the nearly one-year period that the pesticide, malathion, had been sprayed in the area by the State of California Department of Agriculture. A case-control study was then embedded within the cohort to study the effects of

the spraying and of other environmental exposures during pregnancy.[9–11]

An original cohort of 9,564 pregnancies was identified by scanning logs of urine pregnancy tests and pregnancy confirmation visits at the three clinics (Table 1). Pregnancy outcomes were determined from computer linkage to hospital discharge summaries, California birth certificate files, and Kaiser abortion clinic data. For outcomes not obtained from these three sources, individual medical records were reviewed. Records were then re-reviewed for confirmation of all outcomes other than live birth indicated in Table 1. Particular attention was given to determining as accurately as possible the gestation period for each pregnancy.

Of the 9,564 pregnancies, 6,254 survived at least 20 completed weeks and remained under care at one of the three clinics through the time of delivery. Of these, 75 ended in spontaneous fetal death and 6,179 ended in live birth. These form the basis of this study on reporting practices for fetal deaths. Descriptions of the pregnancies ending in fetal death were derived both from medical records at the three clinics and from the program's computerized hospital discharge summaries.

An extensive search was made of state fetal death certificate files to determine whether the fetal deaths had been reported to the state registrar. The search was conducted by manually matching the study subjects to four separate lists of fetal death certificate files sorted by hospital, by mother's last name, by mother's first name, and by date, respectively.

Results

Forty-one of the 75 fetal deaths occurred before 28 completed weeks of gestation (between day 140 and day 195, inclusive) and 34 occurred after 28 completed weeks (day 196 and beyond). Most (37/41) of the 20–27 week fetal deaths were not reported, while most (27/34) of the 28–41 week fetal deaths were reported. Only about half (21/41) of the 20–27 week fetal deaths resulted in an overnight hospitalization of the mother, while most (30/34) of the 28–41 week fetal deaths resulted in overnight hospitalization of the mother. For the 24 fetal deaths not requiring overnight hospitalization all were attended by physicians: nine in the emergency rooms and 15 only in the clinics. Dilation and curettage procedures were performed on 16 of the 24.

Table 2 shows the diagnosis codes for fetal outcome on the mother's computerized hospital discharge summary by fetal death certificate reporting status. Three of the 31 mothers with reported fetal death showed no code for fetal death, or for abortion—only miscellaneous conditions of the delivery such as preeclampsia or premature rupture of membranes. A search for fetal deaths using hospital discharge diagnoses only would miss these cases. For the 20 mothers whose fetal deaths were not reported even though hospitalization had occurred, most had codes for some kind of abortion (spontaneous, missed, elective, molar pregnancy or abortion type unspecified). Four had the appropriate ICD-9 code 656.4 for intrauterine death, three of whom delivered fetuses under 400 grams. Of the 24 other women who were not hospitalized, none of their fetal deaths were reported to the state.

The 31 reported fetal deaths fell into several categories: cord problems, placental problems, abnormal presentation, twin pregnancy, sepsis, complications of toxemia, congenital anomaly, and unknown cause of death. (In only four cases was the cause of death unknown by the attending physician.) None of the reported fetal deaths were described in the medical chart as missed abortion. Birthweights were generally considerably over 400 grams although three were less than or equal to 400 grams. Four of the reported fetal deaths were less than 28 weeks gestation (three at 26 and one at 24 weeks); the remainder were all over 28 completed weeks.

Of the 37 unreported fetal deaths occurring during the 20th through 27th weeks, 28 (76 percent) were referred to in the medical chart as missed or incomplete abortion, one was a molar pregnancy, and the remaining eight were described as complete spontaneous abortions. Delivery weights were generally unknown or not recorded. Two delivery weights, however, were over 400 grams. Both resulted in hospitalization of the mother but with a spontaneous abortion code rather than the intrauterine death code on the hospital discharge summary. Of the seven unreported fetal deaths over 28 completed weeks of gestation, only one was over 400 grams. All were under 34 weeks at the time of expulsion. Five of the seven were referred to in the medical chart as missed abortions with the fetus described as autolyzed, mummified, or macerated. Causes of death were unknown or unspecified in over half of the unreported fetal deaths. Known causes of death, however, were similar to the reported fetal deaths.

TABLE 1—Fetal Outcomes in Cohort and in Fetal Death Study among 9,564 Pregnancies Identified at Three Kaiser Medical Offices, September 15, 1981–June 30, 1982

Fetal Outcome	Number In Cohort	Number in Fetal Death Study[c]
Live Birth	6,759	6,179
Fetal Death ≥20 Weeks	80	75
Fetal Death <20 Weeks	538	—
Induced Abortion for Malformation	5	—
Voluntary Induced Abortion	1,802	—
Ectopic Pregnancy	48	—
Unknown	391[a]	—
Total	9623[b]	6,254

[a]Unknowns were largely due to terminated membership in the Kaiser program.
[b]Includes 114 co-twins and three co-triplets.
[c]Includes all that survived at least 20 weeks and remained under care at one of the three Kaiser facilities.

TABLE 2—Diagnosis of Fetal Outcome on Mother's Hospital Discharge Summary by Fetal Death Certificate Reporting Status

Diagnosis	ICD-9 Code	Reported	Not Reported
Intrauterine death ≥22 weeks	656.4	28	4
Abortion			
Spontaneous	634	—	2
Missed	632	—	8
Elective	635	—	2
Molar pregnancy	630	—	1
Unspecified	637	—	2
Miscellaneous condition of delivery[a]	—	3	1
Not hospitalized	—	0	24
Total	—	31	44

[a]No mention of fetal outcome.

Fetal death ratios (the number of fetal deaths divided by the number of live births per 1,000) were calculated for reported fetal deaths, for hospitalized fetal deaths, and for all fetal deaths (Table 3). For fetal deaths at greater than 28 completed weeks of gestation, there were only small differences between the three nested categories. For fetal deaths defined from the 20th week, the fetal death ratio for all fetal deaths was more than double that for only reported fetal deaths; the ratio for hospitalized fetal deaths was midway between the other two categories.

Discussion

These findings are consistent with other prospective investigations conducted in the United States with follow-up through full term[5–7]: fetal death ratios for fetal deaths beyond 20 weeks of gestation were 40–80 percent higher than the respective state averages. In another study in which follow-up was only through the end of the 27th week,[8] fetal death rates for weeks 20–27 were consistent with the present study.

While death in utero after 20 weeks of gestation seems a simple definition, persons responsible for reporting fetal deaths are either confused by the definition or ignore the requirement. Factors other than time since LMP appear to play important roles in reporting fetal deaths. In the Kaiser data, overnight hospitalization must have occurred for a fetal death to be reported. But even with hospitalization, only 68 percent of fetal deaths over 20 completed weeks of gestation were reported to the state. In contrast, 89 percent of hospitalized fetal deaths over 28 completed weeks were reported. The best predictor of reporting was birthweight, with 93 percent of weighed fetuses delivered over 400 grams being reported.

Reporting practices found in the Kaiser program may be representative of reporting practices elsewhere. Fetal death ratios at Kaiser hospitals based on reported fetal deaths are about average in the state of California.[12] Although guidelines[13] exist to help clarify the difference between fetal death and neonatal death there are no routinely distributed guidelines from the states and counties to help distinguish reportable fetal death from other fetal deaths.

Perhaps physicians may rely more on their obstetric training than on state regulations to determine reportability. *Williams Obstetrics*,[14] a major textbook for obstetric training in this country, emphasizes birthweight as the main criterion for reportability, stating ". . . fetuses weighing less than 500 grams usually are not considered as births, but rather as abortions, for purposes of perinatal statistics." Gestational age is then referred to in terms of equivalency to birthweight.

It is routine practice at Kaiser to offer a woman options for disposition of the body of the fetus if it weighs over 500 grams. Such options are not routinely offered for smaller fetuses.

If the trends in this study are representative of widespread practices, the majority of underreporting of fetal deaths may be due not to negligence or random omissions, but rather to systematic perception of which fetal deaths are reportable. Fetuses under 500 grams may seldomly get reported regardless of time since LMP.

This practice in fetal death reporting may account for the consistently lower rates of fetal death found in studies based on state vital statistics compared to prospective studies based on follow-up of pregnancy cohorts. In the prospective studies, gestational age at outcome is based on time between LMP and expulsion, not on birthweight equivalencies.

TABLE 3—Fetal Death Ratios per 1,000 Live Births

	≥20 Completed Weeks of Gestation	≥28 Completed Weeks of Gestation
Fetal death certificate	5.0	4.4
Hospitalized	8.3	4.9
All fetal deaths	12.1	5.5

ACKNOWLEDGEMENTS

I would like to thank Diana Petitti and Shanna Swan for initiating the various studies of this pregnancy cohort; Bruce Fireman for his helpful comments and encouragement in addressing the problem of fetal death reporting; and Betty Jue for her careful review of medical records.

Funding for this project was provided by the California Department of Health Services and the Community Service Program of Kaiser Foundation Hospitals. Any analysis, interpretation, or conclusions based on these data is not necessarily that of the California Department of Health Services. A preliminary version of this paper was presented at the 115th annual meeting of the American Public Health Association in New Orleans, Louisiana, October 18–22, 1987.

Effects of a Geriatric Nurse Practitioner on Process and Outcome of Nursing Home Care

Robert L. Kane, MD, Judith Garrard, PhD, Carol L. Skay, BA, David M. Radosevich, RNC, MSPH, Joan L. Buchanan, PhD, Susan M. McDermott, RNC, MPH, Sharon B. Arnold, MSPH, and Loyd Kepferle, MEd

Abstract: We compared measures of quality of care and health services utilization in 30 nursing homes employing geriatric nurse practitioners with those in 30 matched control homes. Information for this analysis came from reviews of samples of patient records drawn at comparable periods before and after the geriatric NPs were employed. The measures of geriatric nurse practitioner impact were based on comparisons of changes from pre-NP to post-NP periods. Separate analyses were done for newly admitted and long-stay residents; a subgroup of homes judged to be best case examples was analyzed separately as well as the whole sample. Favorable changes were seen in two out of eight activity of daily living (ADL) measures; five of 18 nursing therapies; two of six drug therapies; six of eight tracers. There was some reduction in hospital admissions and total days in geriatric NP homes. Overall measures of medical attention showed a mixed pattern with some evidence of geriatric NP care substituted for physician care. These findings suggest that the geriatric NP has a useful role in nursing home care. (*Am J Public Health* 1989; 79:1271–1277.)

Introduction

Nursing home care has been the subject of widespread concern and criticism. Within professional circles, it enjoys little prestige. It is viewed as low technology care with little hope of patient improvement and little opportunity to use professional skills.[1] Physician visits tend to be infrequent, conforming to the minimal levels required to authorize the care of residents.[2]

Ironically, when care is provided to nursing home residents they show great responsiveness. In fact, almost any intervention produces a positive response.[3] One promising approach to improve the care of the elderly in nursing homes engages nurses to work as geriatric nurse practitioners (GNPs) to provide or coordinate primary care for residents. An early study in Salt Lake City showed that the geriatric NPs could work effectively as part of a multi-disciplinary team to improve the function of nursing home residents and reduce the costs of hospital care.[4] A study in Boston showed similar improved care and savings were possible.[5]

The enthusiasm of these results has not been matched by patterns of funding. Direct payment for the services of geriatric NPs was not allowed under Medicare Part B if the services were given without on-site physician supervision. Thus geriatric nurse practitioner care in nursing homes was discouraged.

With the support of the W.K. Kellogg Foundation, beginning in 1976, the Mountain States Health Corporation [MSHC] arranged for nurses working in nursing homes throughout four northwestern states to be trained through the continuing education (CE) programs at three nursing schools. The training used the already established CE model of four months of didactic training at the university and eight months of preceptorship with a local physician at the home site. The nursing homes agreed to add the geriatric NPs to their staffs and to allow them to function in the expanded role for which they had been trained. A contract for a minimum of 18 months of employment after training was negotiated, with the geriatric nurse practitioner being an employee of the nursing home rather than an independent contractor or an employee of a physician group. In 1982, the program expanded to cover 13 western states, using four western schools of nursing to provide the continuing education.

After the program was well established, an evaluation of the effect of adding these GNPs on nursing home costs and quality of care was undertaken. The study design had three major components: a prospective study of the functional changes seen in a sample of residents treated by geriatric NPs compared with matched controls, a retrospective review of the records from the geriatric nurse practitioner homes and matched controls, and an analysis of the costs to both payors and nursing homes associated with this innovative approach to care.[6] This paper describes the results of the retrospective study.

Methods

Because the study was mounted after the program was well established, there was no opportunity to design a randomized clinical trial. From the pool of about 100 nursing homes then employing trained geriatric nurse practitioners, 30 pairs were developed by matching each GNP nursing home to a control home in the same state* on the basis of proportion of Medicare cases, ownership, corporate management, number of beds, and rural/urban location. Each potential match required both a GNP home and a control home willing to allow access to records (and for some, patients).

A quasi-experimental design was used, consisting of pre- and post-geriatric nurse practitioner periods for both groups of homes. The data source was the resident's nursing home records. The pre-GNP period consisted of one year prior to the geriatric NPs' employment in that role, and the post-GNP period began *with* the NP's employment and lasted up to two years for any resident (or until the resident was permanently discharged from the home). The training period was not part

of the study. The time periods for the control home coincided with those for the paired geriatric nurse practitioner home. Once these general time periods were established for each sample pair, some minor adjustments were made (never more than a six-month shift) to accommodate the dates of the study to the home's fiscal year in order to link financial and practice data. This time-based sampling allowed a cross-section of periods among the 30 pairs that encompassed more than eight years of practice and changes in the external environment.

Within each nursing home, two samples of residents' records were selected randomly—one for the pre-period and a second for the post-period. The same number of records was sought in each home, resulting in varying sampling ratios depending on numbers of beds and turnover rates. The majority of the homes (or the wings that used a geriatric nurse practitioner) were approximately 100 beds. Within each sample, a 2:1 ratio of newly admitted to longer stay residents was planned; however, it was not possible to achieve this ratio in some cases because of insufficient numbers of newly admitted cases. As shown in Table 1, the final pre-GNP sample was more equally weighted. Because the post-GNP period was two years, a slight variation in the sampling method was used. The sample was divided into the two years but the second year sample added only new admissions.

Demographic information, functional status, nursing therapies, medications, medical attention, and use of hospital and emergency room services were abstracted from the medical records. The general time frame used for this component was to assess the resident's condition on entrance to the nursing home (or the beginning of the study period for long stays) and at discharge (or end of study period). For selected variables, a third status point was used at three months, the median stay for most admissions. For many variables where use varied with time, a two-week window was defined and the rates calculated for that period.

In addition to tabulating numbers of medications given (separated by regular and PRN (as occasion requires) use), specific dose-equivalents of six types of drugs most commonly used in nursing homes were calculated: psychotropics, sedatives, tricyclic antidepressants, diuretics (except furosemide), furosemide, and digoxin.

Orders for various services (medications, laboratory tests, nursing orders, and special services) were tabulated according to the person ordering them and the mode of ordering them (i.e., in person or by telephone). Visits by attending physicians and specialized personnel (podiatrists, dentists, physical therapists, occupational therapists) were tabulated. The frequency of services was calculated as a rate per day of stay in the nursing home. Use of emergency room services was separated by whether the visit was prompted by an emergency or for routine testing. Hospital admissions and lengths of stay were recorded. The data on hospital use are again presented as a rate per day, using the patient's total length of stay in the nursing home as the denominator.

A series of tracers was developed for conditions for which record data might be available (diabetes, congestive heart failure, hypertension, new urinary incontinence, chronic urinary incontinence, feeding difficulty, acute confusion, and fever) to indicate whether appropriate steps in care were taken when potentially indicated. Each tracer was reviewed by a panel of clinicians. Because some judgment is involved in whether these steps are always indicated, different values were assigned to the individual steps by a second panel of physicians, who were independent of the project. The summary tracer scores were then used to compare quality changes across time.

Medical record abstraction was performed by trained registered nurses who were not involved in the original study. A week-long session was held to train and test their abstracting skills. In addition, a field manual was developed. The data collection was supervised by staff of the Mountain States Health Corporation.

Analysis

Analyses focused on whether the pattern of pre-post change in nursing homes employing geriatric NPs differed from that in control homes. In some instances the variable of interest was calculated in terms of the change from admission to discharge (or to the three-month time point). The availability of pre-GNP data minimized the effects of any baseline differences between GNP and control homes. The basic analytic tests used analysis of variance for continuous data and chi-square tests for categorical data. The tests for changes in specific medication use employed repeated measures MANOVA. Specific attention was paid to the problem of outliers and their possible effects on mean values.

Newly admitted residents and long-stay residents were analyzed separately. In order to be sure that the analysis addressed the best examples of geriatric nurse practitioner

effectiveness, the sample was further divided by the extent of GNP role implementation as reflected in interviews conducted with the geriatric nurse practitioners after the evaluation was completed. The GNPs were asked about their role and each practice was classified as full or partially implemented on the basis of the amount of time they reported working on geriatric nurse practitioner tasks. Those working 50 percent or more were considered fully implemented.[7] The results for the fully implemented pairs were calculated in addition to those of the overall sample.

Results

Descriptive Data

As shown in Table 1, data are available on 3,184 cases in the pre-GNP period and on 6,554 cases in the post-GNP period. The pre-GNP ratio of new admissions to long-stay residents is 1.27 for geriatric nurse practitioner cases and 1.63 for control cases. For the post-GNP period the corresponding ratios are 2.0 and 2.2.

Table 1 also compares some basic demographic and historical parameters for the various subgroups. The prevalence of the major chronic disease diagnoses was generally comparable, but among new admissions the GNP residents were more likely to have a diagnosis of dementia in the pre-GNP period and nervous system disease in the post-period. In the post-GNP period, geriatric nurse practitioner residents were more likely to have been admitted from home and less likely to come from the hospital. This same pattern held for long-stayers in both the pre- and post-GNP periods. Not surprisingly, long-stay residents were slightly older than new admissions.

Functional Status

Change in functional status from admission to discharge was calculated as both a continuous score based on the number of domains in which the patient was dependent and a fixed score of change from dependence to independence within each domain. These two approaches allowed for different statistical manipulations but the patterns of overall findings were the same. Table 2 shows that there were few significant differences noted in the extent of change between the geriatric nurse practitioner and control subjects. This table summarizes the differences found among the many analyses performed. Here and in the rest of the tables, the figures presented are the net difference for that variable between GNP and non-GNP from pre to post. The signs indicate the direction of the difference: a positive sign indicates a relative increase in the GNP score compared to the non-GNP from pre to post; a negative sign indicates the reverse.

Case-Mix

Case-mix at the time of admission to the nursing home was measured on the new admissions in three ways: 1) the level of dependence for each of the functional measures shown in Table 2; 2) the frequency of ordered nursing therapies; 3) a case-mix index adapted from that used in Minnesota as a basis for nursing home payment.[8]

Comparisons of individual functional status items on admission showed generally no difference, but in two areas the changes suggested that geriatric nurse practitioner patients were less impaired over time. For the complete sample, more GNP patients were ambulatory and mentally alert. The latter finding was also true for the full implementation subset.

− = GNP group relative decrease

The possible scores at each point in time ranged from 1 to 5 for ambulation, −6 to +6 for change in total number of dependencies, and 1 and 4 for all other variables.

*.05 < P ≤ .10 **.01 < P ≤ .05 ***P ≤ .01.

These patterns were somewhat different when nursing therapies were used as the basis for case mix. Table 3 shows changes from pre to post for the GNP and control groups. Here the signs indicate an increase or decrease in the ratio. The results reveal a pattern of increased use of several activities that call for patient training (e.g., bowel and gait) and restorative nursing in GNP homes. Moreover, the reductions in use of restraints and even soft diets may reflect an effort by the geriatric nurse practitioners to avoid such approaches to enforced dependency.

Figure 1 compares the patterns of the constructed case-mix index, in which possible scores ranged from 1 to 10. Although both the GNP and non-GNP groups showed pre-

post differences, there was little difference in change over time between the groups. The median value for the GNP group was 5.85 in the pre-period and 6.35 in the post-period compared to 5.51 and 5.96, respectively, for the controls. The size of the differences in both means and medians was examined using both ANOVA and various nonparametric tests with the consistent finding of no difference between the GNP and control groups.

Medical Attention

Medical attention was measured in terms of frequency of visits and level of activity. The patterns of change over time are shown in Table 4, where a positive sign reflects a relative increase among GNP groups compared to controls. Among new admissions, there is a substantial reduction in both medication and laboratory orders. The reduction in nursing orders by physicians is reduced when the additive effect of the GNP is considered. By comparing the rates for physicians and the total rates for each service, one can discern a modest pattern of substitution for several services. Interestingly, the rate of physician visits declines for new admissions and increases slightly for the full implementation long-stay residents. There is a consistent pattern of increased physical therapy visits, podiatry, dental care, and occupational therapy, but only the former is significant for the long-stay patients.

Medications

Medication use was examined several ways. The overall number of drugs and doses given was tabulated from the medication sheets, rates were calculated separately for regular administration and PRN use. In addition, dose equivalents were calculated for six common drug classes. These were further analyzed by examining their rate of use with patients who might be expected to require them. The results shown represent changes in the pre-post patterns for differences in use rates from admission to discharge. It is important to appreciate that these summary results can be achieved by either a decrease in post-GNP use or less of an increase.

The summary in Table 5 uses a positive sign to reflect a relative increase for the GNP groups compared to the controls. The numbers shown are differences between GNP and control groups for two-week dosage rates used to summarize the pre-post change in differences from admission to discharge.

The most striking observation is the relative lack of effect. Once again, the differences occur among the long-stay residents of nursing homes rather than newly admitted cases. This overall absence of significant differences resulted from several different phenomena. In some cases, there was truly little shift in usage rates. In others, similar patterns of differences were present for both GNP and controls.

For example, there is much concern about the potential excess use of psychotropic medications among nursing home residents. The net GNP use of psychotropic medication was greater than the controls' for both those with and without disruptive behavior. The GNP mean dose equivalents for psychotropics did not decrease from admission to discharge

for the complete sample, and also ended at a slightly higher level in the post-period than in the pre-period. The control levels did not change from admission to discharge in the post-period and remained at a level below that of the GNP. The GNP overall level of mean dose equivalents for psychotropics in the full implementation sample was lower for the post-period than the pre-period, and decreased within the post-period from admission to discharge. The control level was higher for the post-period than the pre-period.

Tracers

Table 6 shows that in a number of instances the use of GNPs was associated with significant improvements in quality scores. This finding pertains to the newly admitted patients even more than to the long-stay residents. As expected, improvements in quality are somewhat more common among the fully implemented subgroup. In the newly admitted group, positive GNP findings in quality of care are observed in the diabetes and feeding tracers for both, and in the new urinary incontinence tracer in the full implementation sample. Among the long-stay patients, positive effects are found in the congestive heart failure and acute confusion tracers in the full implementation sample and fever in the total sample.

Utilization

There was no difference in the rate of use of emergency rooms for either true emergencies or routine testing. However, the GNP patients were less likely to be admitted to hospital (Table 7). The fully implemented subgroup of new admissions had a significant relative reduction in emergency, elective, and total admissions, based on ANOVA analyses. Total admissions were also significantly reduced for the complete sample of new admissions. The significant relative reduction in emergency and total hospital days occurred among both the full implementation and complete samples of new admissions.

Figure 2 shows the pattern of destinations among those discharged from the nursing homes. Among new admissions, an increased proportion of GNP patients discharged from the nursing home went home. The fully implemented subset of new admissions and long-stay patients were also less likely to be discharged to a hospital.

The discharge patterns were further tested using a series of conditional logistic regression models to control for the effects of other potentially confounding variables including age, source of admission, major diagnoses, payment source, ADL dependencies, and mental status. Separate analyses were performed to examine in sequence the probability of: 1) being discharged dead vs discharged alive or remaining in the nursing home; 2) those alive, going to the hospital or not; 3) those alive, going to the community or not; and 4) those alive and not going to the hospital, going to the community or not. There were no significant differences between GNP and controls during the pre-GNP period. For the post-GNP period the newly admitted GNP residents were less likely to be hospitalized (odds ratio 0.76; confidence interval = 0.59, 0.96) and more likely to be discharged to the community (OR 1.22; CI = 1.02, 1.5). Among the long-stay patients, GNP residents were less likely to be discharged to the hospital. (OR 0.50; CI = 0.34, 0.72).*

Discussion

These data suggest that the geriatric nurse practitioners improved the quality of nursing home care in several impor-

tant areas. The benefits are most evident in the tracer studies, which look at the management of specific conditions. The GNP patients show strong indications of closer attention. When these results are compared with the geriatric nurse practitioners' perceptions of where they were having the greatest impact, the patterns validate the GNPs' observations in some areas. For example, the GNPs felt that they had made a substantial impact in drug and laboratory use,[7] and both areas showed reductions among the new admissions. The data suggest a modest substitution of GNP activity for physician activity. The broader measures, such as changes in functional status, similarly do not show much impact although the GNPs thought they were having an effect there.

The geriatric NPs also thought they were permitting an increasing acute case mix. In fact, case mix acuity increased in both the GNP and control homes, but the change is attributable to external forces rather than to adding a geriatric nurse practitioner. Because the timetable for each home was constant within each pair of homes but different across pairs, the effects of changes brought about by shifts in hospital reimbursement and changes in funding rules for nursing home care were minimized in this analysis. The changes in nursing therapies suggest more nursing attention from the GNPs and possibly less use of undesirable approaches to care, such as restraints.

The geriatric nurse practitioner's potential to save total costs of care is suggested by the data on hospital utilization, especially the reduction in hospital days. The savings occur through fewer hospitalizations and less emergency room use. At the same time, GNP patients are more likely to be discharged home from the nursing home.

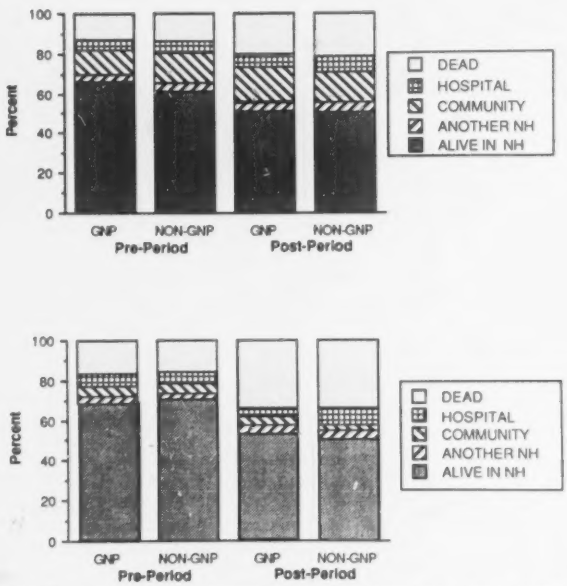

FIGURE 2—Pattern of Discharge Destination by Study Period and Geriatric Nurse Practitioner Status for New Admissions (top figure) and Long-Stay Patients (bottom figure).

The design of the study presents some unavoidable limitations germane to the interpretation of the findings. Although the analysis did control for baseline differences, it cannot control for unmeasured differences between the nursing homes. The homes that undertook this program were adopters and may reflect a more aggressive style of care. The matching did not extend to the level of comparing specific information about staffing ratios.

There were also differences among the GNPs attributable to their individual interests, training, level of physician support, and the administration orientation of their nursing homes. Some of these differences were captured in the interviews with the GNPs, the directors of nursing, and the administrators of the participating homes.[7] To assess the effect of the varied level of implementation of the GNP role, we examined separately those homes where the GNP was primarily performing her intended role and found no consistently different pattern of findings from the total sample.

Taken together, the results of this study suggest that the GNP has a useful and cost-effective role to play in nursing home care. The model tested here relies on the geriatric nurse practitioner as a nursing home employee. It is very possible that GNPs may have an even greater impact if they can operate outside the administrative pressures imposed by this form of sponsorship.

Major Trauma in Geriatric Patients

HOWARD R. CHAMPION, FRCS EDIN., WAYNE S. COPES, PHD, DAVID BUYER, MS, MAUREEN E. FLANAGAN, MS, LAWRENCE BAIN, BS, AND WILLIAM J. SACCO, PHD

Abstract: Contemporary trauma to the elderly, its severity and associated mortality and morbidity in 111 United States and Canadian trauma centers are described. Three-thousand eight-hundred thirty-three (3,833) trauma patients age 65 years or older are compared to 42,944 injured patients under age 65. Although both groups had equivalent measures of injury severity, the older group had higher case fatality and complication rates and longer hospital stays. The results raise important questions regarding the triage, acute care, accurate prediction of outcome, and hospital reimbursement for the elderly injured patient, with implications for care evaluation, quality assurance, and the long-term viability of trauma centers and systems of care. (*Am J Public Health* 1989; 79:1278–1282.)

Introduction

Today, 11 percent of the United States populace (28.5 million persons) are age 65 or older and by the year 2020 this age group is projected to nearly double, reaching about 51 million.[1] In 1984, unintentional injury accounted for almost 24,500 deaths of persons age 65 and older, a death rate of 86.3 per 100,000 population,[2] more than twice the accidental death rate of all ages (39.3) and for 25 to 44 year olds (35.5).

In 1986, 816,000 person age 65 years and older were discharged from short-stay hospitals with a diagnosis of injury or poisoning.[3] Their average hospital stay was 9.8 days, and the number of bed days exceeded 7.9 million, representing 38 percent of hospital bed days for all patients in which injury was the primary cause of admission.[3] At the 1986 average daily costs in hospital ($500) and in intensive care units (ICU) ($1250–$2000),[4,5] their hospital expenses exceeded $4.4 billion. Increased hospital costs due to longer lengths of stay in hospital and ICU, and more frequent complications,[6,7] are factors contributing to the elderly's disproportionate consumption of approximately one-third of the health care resources expended on trauma care.[8]

Although injury to the elderly consumes a significant proportion of trauma care resources, research has focused on the pediatric and young adult populations. Research has produced quantitative indices of injury severity such as the Trauma Score[9] and the Pediatric Trauma Score,[10] but no comparable scales have been developed specifically for the elderly. A comparative study, however, has shown that the injured elderly differ from their young counterparts in injury etiology, mortality, complications, and cost.[11] A comprehensive picture of injury to the elderly has not emerged and the implications for health care planning remain largely unknown, unquantified, or dimly perceived.

Since 1982, numerous North American hospitals have submitted data and information for seriously injured patients to the Major Trauma Outcome Study (MTOS),[12] sponsored by the American College of Surgeons Committee on Trauma. Data are analyzed periodically and confidential results are sent to participating institutions to support outcome evaluations and quality assurance activities.

This paper compares data from the older (≥65 years) and younger (<65 years) MTOS patients to identify the differences between the two groups and the implications for injury prevention, triage, treatment, outcome evaluation, reimbursement, and additional research.

Methods

Data Base

The MTOS data base includes demographics, cause of injury, injury severity, complications, and outcome information for submitted patients. Detailed text injury descriptions obtained at discharge or death are provided based on surgical examination, x-ray, computerized tomography (CT) scan, and/or autopsy.

Data from 3,833 patients 65 years or older (the "older group") and 42,944 patients less than 65 years (the "younger group") were analyzed. Patient data were submitted from 1982 through 1986 by 111 US and Canadian hospitals participating in MTOS. Ninety-five participants (85.6 percent) reported being Level I or Level II trauma centers.

MTOS participants are required to identify a physician site director and nurse coordinator who are responsible for overseeing data collection, data quality and completeness, and data submission to the study analysis site. The MTOS packet describes the periodic reports prepared for participants, provides operational definitions for each data element, defines the specificity required of anatomic injury descriptions, and suggests sources for data abstraction, i.e., physician and/or operative notes and CT reports.

Collected data are forwarded to a study analysis center in Washington DC, where experienced coders check for data face validity, ensure essential data have been reported, and check the adequacy of submitted injury descriptions for coding. Anatomic injury descriptions are coded according to the International Classification of Disease taxonomy (ICD-9-CM)[13] and for severity using the 1985 version of the Abbreviated Injury Scale (AIS).[14] Data are keypunched, verified, and corrected for analysis. Extensive computer quality control checks are intended to minimize coding errors and to ensure the accuracy, completeness, and consistency of submitted data. When necessary, participants are asked to confirm, clarify, or supplement vague information or missing or unusual data.

Indices of Injury Severity

Patient physiologic status on emergency department arrival is characterized by the Revised Trauma Score (RTS),[15–17] a function of admission values of the Glasgow Coma Scale (GCS), systolic blood pressure (SBP), and

respiratory rate (RR) (Appendix). The RTS takes values from 0 to 7.8408. Lower RTS values are associated with poorer prognoses.

The RTS replaced the Trauma Score (TS)[9] as the MTOS physiologic severity index. Development of the RTS was motivated by TS limitations; the TS underestimates severity for some head-injured patients and includes variables difficult to obtain in the field (capillary refill and respiratory expansion). The RTS has been shown to be a more reliable predictor of survival/death outcome than the TS.[15]

Anatomic injury severity is measured by the Injury Severity Score (ISS),[18] an index derived from the Abbreviated Injury Scale (AIS)[14] severity scores for individual injuries. The ISS takes values from 1 to 75. Higher scores generally indicate more severe injuries. Studies have shown that the ISS is correlated with mortality; lower correlations have been observed between ISS and length of hospital stay and disability.[18–20]

MTOS survival probability norms are based on the TRISS index.[16,21] TRISS is a severity index which includes the RTS, ISS, and patient age. The mathematical form of the norms is the logistic function $P_s = 1/(1 + e^{-b})$ in which P_s is patient survival probability, $b = b_0 + b_1(RTS) + b_2(ISS) + b_3(AGE)$. Age is 0 for patients <55 years, and 1 for patients ≥55 years of age. The "b"s are regression weights.

TRISS norms are used in the PRE (preliminary outcome evaluation) methodology to support quality assurance activities. Patient ISS and RTS scores are plotted on a scatter diagram (Figure 1). Patients whose coordinates are on the diagonal line (determined by setting b = 0 in the norm equation) are estimated to have a 0.50 survival probability. Coordinates above (below) the line have estimated survival probabilities that are less than (exceed) 0.50. In Figure 1, survivors (L = living) above the line and non-survivors (D = dead) below it represent patients with unexpected outcomes, suggested by the American College of Surgeons to be worthy of peer review.[17]

Statistical Analysis

Statistical comparisons of attributes or outcomes of the older and younger patient samples use the chi-square test for frequencies and z-tests for comparisons of means.

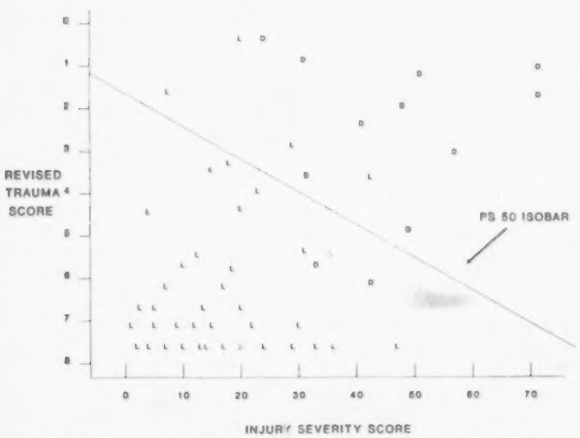

FIGURE 1—Example of a PRE (Preliminary Outcome Evaluation) chart
Key: L = Living
D = Dead

Results

Elderly study patients had a mean age of 76.3 years (sd = 7.8, range 65 to 104 years). Mean age for the younger group was 28.1 years (sd = 13.4, range 1 to 64 years). The male/female ratios for the older and younger groups were .93 and 3.3. The respective mortality rates were 19.0 percent (727/3,832) and 9.8% (4,180/42,860).

Distributions of cause of injury and their associated case fatality rates differed substantially (Table 1). Falls were the most frequent cause of injury to the elderly and had the lowest mortality rate. Motor vehicle accidents, the most prevalent cause of injury in the younger group, was the second most frequent cause of injury to the elderly. Gunshot wounds resulted in the highest case fatality rates in both groups. The elderly showed statistically higher case fatality rates in all etiological categories, except motorcycle injuries and "unknown," for which elderly samples were small.

The severity of anatomic injury and admission physiology as measured by average values of ISS and RTS were not statistically different for the two groups. Mean ISS values were nearly equal for the older and younger groups (13.3 and 13.4, respectively) and mean RTS values were equal (7.0). The difference between the mean ISS values for elderly and young non-survivors (24.1 and 30.2) is substantial, however (6.1, 95% confidence intervals 7.1, 5.1). Elderly non-survivors had a mean RTS at emergency department admission of 4.6, the younger non-survivors had a mean RTS of 2.8 (difference 1.8, 95% CI 2.0, 1.6).

Survival rates for injuries to specific body regions by maximum severity levels are given in Table 2. For example, of patients whose most severe injury was AIS 3 to the thorax, 83.8 percent of the elderly patients survived compared to 95.2 percent of the younger patients. (In Table 2, a patient's outcome is included in the results for each body region sustaining an injury of maximum severity. Thus, the cell entries in a row may not be independent.) The proportion of elderly who died was higher for every severity level/body region combination; differences were especially marked for abdominal injuries (11.5 percent fatality in the younger group and 29.5 percent in the older group). A high proportion of head injuries died in both groups.

Table 3 gives proportions of deaths and complication by ISS interval for the two groups. Mortality increased with higher ISS scores for both patient groups. For every interval, the percentage of deaths of the older group was higher than those of the younger group; the difference was generally greater for ISS values of 25 or more. For ISS values <25

50–74	90.5/61.9	65.2/42.6
75	94.4/38.9	89.9/25.3

(relatively minor or single system injuries), proportions were 9.9 percent and 3.3 percent for older and younger patients, respectively. For patients with an ISS >50 (severe multisystem injuries), most cases in both groups died (92 percent older versus 78 percent younger).

Complications for older (33.4 percent) and for younger patients (19.4 percent) are also very different. Pulmonary complications were most frequent in both groups. Cardiovascular complications were much more common in older patients (9.8 percent) than younger patients (2.1 percent). Complications were substantially more frequent at the less severe ISS intervals for elderly patients than for younger patients.

There were 5.5 percent of blunt-injured MTOS patients and 3.8 percent of patients with penetrating injuries who had "unexpected" outcomes according to TRISS projections (Figure 1). Most striking are those at the extremes of the survival probability scale: 465 unexpected MTOS deaths had estimated survival probabilities exceeding .90. Approximately 30 percent of those patients were ≥65 although the elderly represent only 8.2 percent of all MTOS patients. Most of those patients had no major injury (AIS >3) and had excellent physiology when admitted to the emergency department.

Survivors and non-survivors in the older group had substantially longer average lengths of stay in the hospital and in the ICU than the younger group (Table 4).

Discussion

MTOS findings confirm those of other studies which have shown that the elderly are more vulnerable to injury than their younger counterparts, die more frequently, and have longer hospital stays for injuries of comparable severity.[22,23] This increased vulnerability has in part altered the perception that injury is a disease of the young who, because of the focus on years of productive life lost, have been the beneficiaries of research efforts and health policy thrusts. The magnitude of the problem of injury to the elderly is now being more fully recognized. By 1995, 35 million US citizens will be more than 65 years old. At the current elderly injury mortality rate (86 per 100,000) 30,100 elderly people will die from injuries in 1995. Further, recent studies suggest that trauma is underreported and represents a more prevalent cause of death in the elderly than is officially recognized.[24] The high costs of hospitalizing and treating the elderly are motivating health care providers to examine the efficacy of injury prevention programs and trauma care.

TABLE 4—Mean Length of Hospital and ICU Stay (Days)

Age (years)	Survivors		Non-Survivors	
	Hospital	ICU	Hospital	ICU
≥65	15.7	3.1	9.9	6.0
<65	12.2	2.6	4.2	3.1

There are, however, few reported studies of injury to the elderly and most of those have limited sample sizes. The MTOS thus provides a unique opportunity to study a large number of contemporary, elderly injured. The entire MTOS patient sample represents approximately 0.4 percent of all injured patients hospitalized in the United States, approximately 1.0 percent of all trauma deaths, and 2.0 percent of all in-hospital trauma deaths during the four-year study period. Although the MTOS patient sample is not population based and biased toward the more severely injured patients (more than 85 percent of participating institutions are Level I or Level II trauma centers), the data base focuses on those injuries that are most costly, require a large consumption of health care resources, and perhaps have the greatest impact on the utilization and delivery of trauma care and the formulation of prevention programs.

For example, although falls are the most frequent cause of injury in the elderly, automobile injuries (motor vehicle and pedestrian) result in the most deaths in this age group. The 20.7 percent mortality rate in MTOS for elderly victims of motor vehicle trauma (versus 9.6 percent in the younger group) substantiates the toll of this category of injury. Strategies such as driver improvement programs have been designed to reduce the incidence of motor vehicle deaths in older people, and some state motor vehicle departments and insurance companies have reported a lower incidence of fatalities and collisions from these programs.[25,26] Gunshot wounds, however, are only dimly perceived as a problem in this population. Although the incidence (5.5 percent) is much lower than other injuries, more than half the MTOS gunshot victims age 65 and older died. The rising homicide rate in many cities and higher risk of elderly suicide portend a problem of possibly greater proportions that could require a more focused prevention/treatment strategy.

At the other end of the spectrum are injuries of lesser

severity such as hip fractures, which are often the result (or the cause) of falls in the elderly. The MTOS data base showed an increasing mortality with age in patients whose only injury was a hip fracture. An injury that is easily survivable in the younger population can result in life-threatening consequences for the older group. Identifying such specific causes of vulnerability in the elderly group can target areas for treatment and prevention programs.

A precise characterization of the injury severity of the elderly is as yet unavailable. MTOS outcome prediction results are subject to limitations of the ISS, which have been described,[27] and of the AIS, which assigns severity scores to individual injuries, independent of patient age. Also, investigations of the relation between physiologic scores, such as the RTS, and survival rate among elderly patients have not been reported. Although current injury characterizations include the effect of patient age in a coarse way, factors such as pre-injury illness, disease, or functional level are not considered. These are particularly germane to the elderly group whose susceptibility to complications are well known and who can be at greater risk of dying even when physiology appears normal. The importance of these factors in the characterization of injury to the elderly suggests that more accurate predictions of outcome are possible and necessary. This has been recognized in the pediatric population, for whom a review and reassessment of their AIS scores have already been accomplished.*

MTOS data currently include patient outcomes for survival/death and length of stay in hospital and in ICU. Because of cost and limited resources, most participants cannot perform post-discharge functional assessments, although selected elements of the Functional Independence Measure (FIM)[28] are now being collected. With the limited outcome data, an assessment of the efficacy of trauma center care for the elderly is difficult; refinements are not possible, e.g., determining whether the center benefits elderly injured patients in general or only certain subsets. Such findings could have important system applications such as formulating guidelines for triage. The substantial number of blunt-injured, elderly, "unexpected deaths" identified in MTOS suggests the need to review existing triage criteria endorsed by the American College of Surgeons Committee on Trauma (ACSCOT).[29] Those criteria are based on values of RTS variables and mechanism of injury information. Patient age is mentioned, but unemphatically.

The need for a better understanding of whether the elderly benefit from trauma center care is fueled by the growing emphasis on health care cost containment. Under the prospective payment system, hospital reimbursement is based on DRGs, sets of medically similar diagnoses with approximately equal lengths of stay. Because of the heterogeneity of trauma patients, their hospital stays are bimodal and not well represented by the DRG average. A study of hospital lengths of stay for Maryland patients of all ages with trauma-related DRGs found substantially more variation than for non-injury DRGs considered by many to be the most variable under the system.** Researchers have also noted that among the 469 DRGs, only 96 are adjusted for the elderly. MTOS data suggest the effect of age for all levels of injury severity, and therefore across many diagnoses. Several other analyses suggest that the current system could undermine the financial viability of trauma care systems.[30–32]

MTOS findings indicate that the effect of trauma to the elderly is more serious than to the younger population. The perception of injury as a disease of the young and the use of inadequate physiologic and anatomic indices for this population fail to recognize how trauma affects the elderly and how trauma centers and systems can most effectively be utilized in their care. The elderly, because of their growing numbers, vulnerability to injury, and the significant cost of their trauma care, should be a new focus for trauma research and health policy examinations.

APPENDIX

Revised Trauma Score

Motivated by insights from audits of patients with "unexpected outcomes" identified in the September 1985 MTOS analysis, the Trauma Score (TS) was modified. The Revised Trauma Score (RTS) includes the Glasgow Coma Score (GCS), Systolic Blood Pressure (SBP) and Respiratory Rate (RR).

RTS VARIABLE BREAK POINTS
CODED VALUES

GCS	SPB	RR	Coded Values
13–15	>89	10–29	4
9–12	76–89	>29	3
6–8	50–75	6–9	2
4–5	1–49	1–5	1
3	0	0	0

Each variable takes on coded values from 0 to 4 based upon its raw value. The break-points defining coded values are given below.

Empirically derived weights were obtained for each coded variable from a regression analysis of data from 26,011 consecutive patients from 51 MTOS "norm" institutions. The RTS is defined as

$$RTS = .9368\ (GCS_c) + .7326\ (SBP_c) + .2908\ (RR_c)$$

where the subscript c indicates coded value.

HRSA Provides Financial Aid to Disadvantaged Students in the Health Professions

More than $5.3 million in grants were awarded recently by the Health Resources and Services Administration (HRSA) to 193 schools in 45 states, the District of Columbia, and Puerto Rico to provide financial assistance to disadvantaged students of medicine, dentistry, or osteopathy. The schools are responsible for selecting students to be assisted. Students from disadvantaged backgrounds who meet exceptional financial need criteria are eligible for support. The aid grants carry no service or financial obligations and may be used for tuition and other reasonable educational expenses. Institutions receiving grants are located in all states except Alaska, Delaware, Idaho, Montana, and Wyoming.

Additionally, grants totaling more than $6.5 million were awarded by HRSA to 298 health professions schools in 46 states, DC, and Puerto Rico to provide scholarships for students in exceptional financial need. Participating schools will award the scholarships to support students of medicine, osteopathy, dentistry, optometry, pharmacy, podiatric medicine, and veterinary medicine during the 1989–90 school year. Those individuals eligible for these scholarships are students in any class year whose resources do not exceed the lesser of $5,000 or one-half the cost of school attendance. The scholarships carry no service or financial obligations. Institutions receiving scholarship funds are located in all states except Alaska, Delaware, Montana, and Wyoming.

For further information about either of these student aid programs, contact Blake Crawford, Health Resources and Services Administration, USPHS, DHHS, 5600 Fishers Lane, Room 14–43, Rockville, MD 20857. Tel: 301/443-3376.

Relation between Vegetarian/Nonvegetarian Diets and Blood Pressure in Black and White Adults

CHRISTOPHER L. MELBY, DHSc, MPH, DAVID G. GOLDFLIES, MS, GERALD C. HYNER, PhD, AND ROSEANN M. LYLE, PhD

Abstract: We examined the possible interaction of race and diet on blood pressure (BP) in volunteer Black Seventh Day Adventists compared to volunteer White church members. Height, weight, waist and hip circumference, and resting seated BP were recorded in Black vegetarians (n = 55; age: 54.7 ± 16.9 yrs), Black nonvegetarians (n = 59; 56.1 ± 14.1 yrs), White vegetarians (n = 164; 52.2 ± 16.7 yrs), and White nonvegetarians (n = 100; 52.6 ± 15.6 yrs) attending a regional conference. Forty-four percent of the Black nonvegetarians were medicated hypertensives, compared to only 18 percent of the Black vegetarians, 7 percent of the White vegetarians, and 22 percent of the White nonvegetarians. Black vegetarians exhibited lower age and sex-adjusted systolic BP ($\bar{x}$ = 122.9/74.4 mm Hg) than Black nonvegetarians ($\bar{x}$ = 132.2/75.9 mm Hg). After further adjusting BP for body mass index and waist/hip ratio, the systolic BP among Black vegetarians remained lower (122.8) than Black nonvegetarians (129.7) but higher than that of the Whites who showed no diet-related BP differences. (*Am J Public Health* 1989; 79:1283–1288.)

Introduction

Several dietary constituents including sodium,[1–3] total calories,[4] saturated fat,[5] and alcohol[6,7] have been shown to be positively related to blood pressure (BP). Potassium,[8] calcium,[9,10] magnesium,[11] polyunsaturated fat,[12] and fiber[13] appear to be inversely related to BP. The vegetarian diet tends to be low in the factors positively related to BP, and high in the protective factors (except for calcium in the diet of strict vegetarians who consume no dairy products). Cross-sectional studies of White adults in Australia,[14–16] Israel,[17] and the United States[18–20] have found lower BP among vegetarians than nonvegetarians. Estimates from these studies of the magnitude of the blood pressure differences attributable to diet may be inaccurate because of the lack of random selection of subjects, and group differences in the use of alcohol, caffeine, and tobacco; physical activity; psychosocial stress; weight,[21] body mass index (BMI),[16,19] or anatomic location of body fat.[22] Despite the shortcomings of these observational studies, several experimental studies have been conducted which demonstrate a modest BP-lowering effect when omnivores are switched to a vegetarian diet.[23,24] In these trials a placebo effect cannot be excluded since subjects were not blind to the type of diet consumed.

Whether the vegetarian diet protects against elevated BP has not been studied in US Black adults, a population with a high prevalence of hypertension, possibly due to genetic susceptibility.[25] We compared BP in a group of Black adults following a vegetarian diet to that of a group of Black nonvegetarians. We also explored the possible interaction of dietary preference and race by examining BP in a sample of White vegetarians and nonvegetarians. To reduce the confounding effects of alcohol, caffeine, and tobacco, we studied members of the Seventh Day Adventist Church which encourages avoidance of these substances.

Methods

Subjects

Subjects for this study were volunteers from members of the Seventh Day Adventist Church, who were in attendance at either of two conferences which took place in Michigan during July 1987. The first conference was composed of mostly Black conferees from the midwest region of the US and the second was attended primarily by White church members.

All of the Blacks attending the first conference were requested to participate in this study. Conferees were informed that the purpose of the study was to examine the relation between health habits and health risks. Anonymity and confidentiality were assured; the study was approved by the Committee for the Protection of Human Subjects at Purdue University. Because hypertensives and the elderly might have been more prone to participate, special effort was made to inform the Black conferees that *all* adults were requested to participate, regardless of age or health status. Approximately 50 percent of the Black women volunteered, compared to 20 percent of the Black men. Table 1 provides the demographic characteristics of the 114 Black study participants (89 females, 25 males).

In order to obtain a comparable group of White Adventists, with a sex distribution similar to that of the Black sample, a gender-stratified random sample was recruited from those in attendance at the second conference. From the 400 randomly selected subjects (approximately 80 percent women, 20 percent men) 264 agreed to participate. The characteristics of the 264 White subjects (222 females, 42 males) are also included in Table 1. The average age for all four groups was between 52 and 57 years, and the majority of individuals in each group were long-time church members. The Whites had a longer family history of Adventist church membership than the Blacks, and the White vegetarians had slightly more years of formal education than the other three groups. The average length of adherence to a meatless diet was 20.6 years for Black vegetarians (n = 55) and 27.2 years for White vegetarians (n = 164). Black nonvegetarians (n = 59) averaged 10.1 ± 1.9 ($\bar{x}$ ± SEM) three-ounce servings of meat, poultry, and fish per week, while White nonvegetarians (n = 100) consumed 3.6 ± 0.4 servings of flesh food per week.

Dietary Measures

Subjects were given a comprehensive health questionnaire adapted from previous studies[19,20] and scheduled for measurement of BP and anthropometric characteristics within a four-day period. Subjects categorized themselves as vegetarian (no consumption of meat, fish, or poultry) or nonvegetarian and answered a food frequency questionnaire (Right Byte Nutritionist III, N-Squared Computing, Silverton, Oregon) composed of 141 food items and related food

	Black Adventists		White Adventists	
	VEG (n = 55)	NVEG (n = 59)	VEG (n = 164)	NVEG (n = 100)
Age (yrs)	54.7 ± 2.3	56.1 ± 1.8	52.4 ± 1.3	52.6 ± 1.6
Education (yrs)	12.8 ± 0.52	12.8 ± 0.4	13.9 ± 0.2	12.5 ± 0.2
Church member (yrs)	28.7 ± 2.5	29.2 ± 2.6	37.0 ± 1.4	31.2 ± 1.8

groups, to which the subjects reported the amount and frequency of their usual consumption during the previous three months. Included among the listed food items in the instrument are several commercially prepared soy-protein meat analogs frequently used by Seventh Day Adventists. Dietary responses were analyzed using the data base from US Department of Agriculture[26]; macro- and micronutrient intakes were estimated for each subject. Complete dietary data were obtained for 352 of the 378 respondents.

Blood Pressure Measurement

Following a five-minute rest, two seated BP measurements were taken for each subject using a random-zero mercury sphygmomanometer (Hawksley and Sons, Ltd., London) by trained personnel blind to the subject's dietary preference. The second BP measurement was taken two minutes after the first. The first and fifth phase Korotkoff sounds were recorded as systolic and diastolic pressure, respectively. The average of the two BP measurements was used for statistical analyses, regardless of the subject's use or non-use of antihypertensive medications. Subjects were not informed of their BP values until both measurements were recorded.

Anthropometric Measurements

Following the BP measurements, height, weight, triceps skinfold, and waist and hip circumference were assessed. Height without shoes was measured to the nearest one-quarter inch using a stadiometer and converted to centimeters. Subjects were weighed wearing lightweight summer clothing on a balance beam scale. Two triceps skinfold measurements were taken using a Lange skinfold caliper (Cambridge Scientific Industries, Cambridge, MD) and the average was used for statistical analyses. Waist circumference was measured in centimeters using a nonstretchable tape at a level estimated to be midway between the xyphoid process of the sternum and the umbilicus in women, and at the level of the umbilicus in men. Hip circumference was measured in centimeters at the widest hip girth. All circumference measurements were taken without removal of subjects' clothing.

Statistical Analyses

All statistical analyses were made using the Statistical Analysis System (SAS, Cary, NC). Group means of demographic data and anthropometric characteristics were compared using the one-way analysis of variance procedure. Blood pressure data were analyzed with a two-way (diet by race) analysis of covariance, using age, gender, BMI (Wt/Ht^2), waist/hip ratio, and family history of hypertension as covariates. Frequency data were analyzed using the Chi Square statistic. Relationships between variables were examined using simple and multiple correlational analyses.

Results

Intake of macronutrients and several micronutrients of interest are revealed in Table 2. Macronutrient differences between vegetarians and nonvegetarians were as expected, with vegetarians exhibiting lower intakes of protein and fat and higher intakes of carbohydrates. Dietary differences were greater between Black vegetarians and nonvegetarians, than between White vegetarians and nonvegetarians.

As shown in Table 3, Black nonvegetarians exhibited significantly greater body weight, BMI, and waist and hip circumference than the other three groups. The differences

Triceps skinfold (mm)	22.1 ± 1.4	32.0 ± 1.9	24.3 ± 0.8	31.1 ± 1.3

between Black vegetarians and nonvegetarians were greater than the differences between the corresponding White groups.

None of the subjects reported current use of cigarettes or tobacco in any form. None of the Black participants consumed alcohol, and only two White nonvegetarians and one White vegetarian reported any use of alcohol. Caffeine consumption averaged less than 45 mg per day for all four groups. Reported levels of occupational physical activity were not different between the four groups. However, Black nonvegetarians reported lower frequency of participation in leisure-time exercise ($\bar{x} \pm$ SEM = 1.4 ± 0.3 sessions per week of aerobic exercise lasting at least 20 minutes per session, compared to the Black vegetarians (2.6 ± 0.3), White vegetarians (2.5 ± 0.2), and White nonvegetarians (2.0 ± 0.2).

Forty-four percent of Black nonvegetarians reported use of physician-prescribed antihypertensive medication compared to only 18 percent of the Black vegetarians, 7 percent of the White vegetarians, and 22 percent of the White nonvegetarians. A higher percentage of Black nonvegetarians (76.3 percent) reported a history of hypertension among their immediate family members (children, siblings, and/or parents) compared to Black vegetarians (55.6 percent), White vegetarians (45.1 percent), and White nonvegetarians (55.0 percent).

Table 4 shows the age- and sex-adjusted systolic and diastolic BP for the four groups. The p-values for main effects of race (Black vs White) and diet (vegetarian vs nonvegetarian) were both less than 0.05 for systolic BP, and there was a weak race by diet interaction ($p = 0.08$). Black vegetarians had lower systolic BP (122.9) than Black nonvegetarians (132.2) but higher than both White vegetarians (113.6) and White nonvegetarians (116.2). Diastolic BP varied with race but not diet. Adding body mass index and waist/hip ratio as covariates, either alone or in combination, attenuated the BP differences between the vegetarians and nonvegetarians, although the patterns are very similar to those adjusted only for age and sex. The addition of family history of hypertension as another covariate in the model did not significantly alter these results for either systolic or diastolic BP.

Table 5 displays the simple correlation coefficients for BP and selected subject characteristics. Age and anthropometric measures were the best single predictors of systolic BP among both the Black and White groups. Waist/hip ratio was a better predictor of both systolic and diastolic BP than was BMI. None of the macro and micronutrient intakes contained in Table 2 (expressed in absolute amounts or per 1000 Kcal) were significantly correlated with BP ($p < 0.01$), nor was the sodium/potassium ratio. For the correlation analyses, the variable "diet" was expanded to four levels by classifying individuals according to four dietary categories based on use of foods derived from animal sources: strict vegetarian; lacto-ovo or lacto vegetarian; prudent diet (use of milk and eggs, and flesh foods no more than three days per week); and omnivorous diet (liberal use of milk and eggs, and flesh foods on a regular basis). Among Blacks, diet was positively

associated with BP in the simple correlation analyses, but was not among the Whites, possibly owing to their more homogenous diet.

Stepwise multiple regression analysis was performed using variables significantly related to BP in the simple correlation procedure as well as dietary intake of fat, total fat, sodium, potassium, sodium/potassium ratio, calcium and magnesium. Age, race, waist circumference, and family history of hypertension were the best predictors of systolic BP for all subjects. Race, waist circumference, and family history of hypertension were the best predictors of diastolic BP. The unadjusted positive correlation between diet and BP was partly explained by the effects of waist circumference and waist/hip ratio. None of the specific nutrients significantly contributed to the prediction of blood pressure in the multiple regression analysis.

Discussion

The results obtained from the Black participants in this study parallel those of several previous studies of White adults showing that vegetarians exhibit lower BP than nonvegetarians independent of differences in anthropometric characteristics.[14–17] Systolic BP differences between the two Black groups would likely have been even greater had not significantly more Black nonvegetarians had their high BP attenuated by use of antihypertensive medications compared to the Black vegetarians. The lack of significant differences in BP between the White dietary groups may have been the result of inadequate dietary heterogeneity. White Adventist nonvegetarians eat a more prudent diet than the usual omnivore, as evidenced in this study by their average consumption of only three to four, three-ounce servings of meat, fish, or poultry per week, fewer than 300 mg dietary cholesterol per day, and less than 34 percent of calories as fat. Indeed their diet is more similar to the vegetarian diet than that of omnivores in previous studies.

Dietary differences were greater between the Black vegetarians and nonvegetarians which may explain the lower systolic blood pressure in the former, even after adjustment for anthropometric characteristics. The positive association between systolic blood pressure and diet (at four levels of animal food consumption) provides supporting evidence. Possibly the systolic blood pressure difference between Black dietary groups was related to better blood pressure control among the medicated Black hypertensive vegetarians ($\bar{x}$ BP = 136/74) compared to Black nonvegetarians on antihypertensive therapy ($\bar{x}$ BP = 145/79). However, all but two hypertensive subjects (one vegetarian and one nonvegetarian) reported adherence to prescribed medications. Other studies suggest the vegetarian diet may reduce the effective drug dosage for medicated hypertensives.[27]

Despite similarities in age, anthropometric characteristics, exercise habits, and reported levels of stress, Black vegetarians still exhibited a higher prevalence of diagnosed hypertension and a higher average systolic and diastolic blood pressure than White vegetarians. In comparison to White vegetarians, the Black vegetarians had significantly lower mean intakes of potassium, calcium, vitamin D, and magnesium, all of which have been reported to be inversely related to blood pressure.[8–11,28,29] However, the correlational analyses provide no support for their contribution to the blood pressure differences. The absence of a clear nutrient effect, while somewhat puzzling, has also characterized other studies of vegetarian diet and blood pressure. Limitations of questionnaire data are an obvious source of some misclassification, but even controlled dietary trials by Sacks, *et al*,[30] have had difficulty in identifying specific foods and nutrients responsible for the lower blood pressure among vegetarians. They concluded that lower intakes of total fat,

saturated fat, and animal protein, and higher intakes of carbohydrates, polyunsaturated fatty acids, and vegetable protein do not alone explain the lower blood pressure in vegetarians compared to nonvegetarians. In addition, based on experimental findings, Margetts, *et al*,[31] have concluded that the vegetarian diet does not affect blood pressure by way of its high fiber content.

The Australian research group, which has performed numerous studies regarding diet and blood pressure, finds strong evidence for an independent blood pressure-lowering effect of a vegetarian diet, but considerable uncertainty as to the nutrients responsible for this effect.[32] Multiple nutrients may act in concert, with the effect on blood pressure due to the totality of the vegetarian diet, rather than single dietary constituents. Cross-sectional analyses commonly find little or no correlation between specific nutrients such as sodium and blood pressure.[33] This may be partly explained in our study by attempting to relate only current nutrient intake (previous three months) to blood pressure when habitual nutrient intake over several years or even decades would appear to have a stronger influence on blood pressure. The inclusion in the regression analysis of BP values achieved by use of antihypertensive medication could also mask significant dietary correlates of blood pressure. Although attempts were made to minimize non-dietary group differences by sampling only from among Adventist church members, possibly self-selected vegetarians differ systematically from nonvegetarians in attributes not measured in this study, which might be important determinants of blood pressure.

Among both Black and White Adventists, central adiposity as estimated by waist circumference or waist/hip ratio was a stronger predictor of blood pressure than was BMI or peripheral adiposity estimated by triceps skinfold or hip circumference. Dietary preference was related to fat patterning with vegetarians of both races exhibiting less central deposition of fat as estimated by waist circumference and waist/hip ratio. The lower weight and adiposity among Black vegetarians compared to nonvegetarians appears to be at least partly explained by differences in caloric intake and frequency of exercise. However, White vegetarians were significantly leaner than White nonvegetarians despite similar intake of calories and reported exercise frequency. Factors other than total caloric intake and physical activity are known to influence body weight including dietary composition, resting metabolic rate, postprandial thermogenesis, and adaptive thermogenesis.[34] Virtually all studies to date have reported vegetarians to weigh significantly less than nonvegetarians, yet the specific reasons for this difference are unclear. A recent study from our laboratory suggests the lower body weight of vegetarians is not due to higher resting metabolic rate or postprandial thermogenesis compared to nonvegetarians.[35]

In summary, it appears that while there is a relationship between dietary preference and blood pressure in Black adults, the vegetarian diet does not completely attenuate their apparently greater susceptibility to hypertension compared to Whites. However, from a public health perspective, the vegetarian diet appears to have implications for the primary prevention of hypertension and obesity for both Black and White adults. Because such a diet is not easily adopted by the majority of adults in the US, future research must continue the search for the specific dietary factors which afford protection against abnormal elevation of both blood pressure and body weight.

ACKNOWLEDGMENTS

The authors wish to express thanks to R.C. Brown, Sr, Executive Secretary of the Lake Region Conference of Seventh Day Adventists, and to John Swanson, Health Director of the Michigan Conference of Seventh Day Adventists, for their cooperation in conducting this study; and to Kristen Geuss for her assistance in analyzing the dietary data. An earlier version of this research was presented at the 28th annual meeting of the American Society for Clinical Nutrition, April 28–30, 1988, Washington, DC. Supported by an XL Grant from the Purdue University Research Foundation.

Births to Older US Women: NCHS Report

Detailed statistics on first births to older US women are now available from the National Center for Health Statistics in a new report, *Trends and Variations in First Births to Older Women, 1970–86*. Statistics in the report focus on the decline in childbearing among well-educated women in their twenties, and the extent to which these women have delayed motherhood. Maternal and infant health characteristics are also analyzed. Highlights of the report include:

- First births to women in their thirties have increased substantially since 1970, quadrupling their levels in a 16-year period. Throughout the 1970s, the increases were largest for women ages 30–34 years. Since 1980, the impact of this phenomenon has shifted to older women. Between 1980 and 1986, the increases in first births and first-birth rates were much greater for women ages 35–39 years.
- During this period of rapidly rising first-birth rates for women in their thirties, rates for women in their teens and early twenties declined.
- The number of women in their thirties grew substantially during this period—all born in the post World War II baby boom years.
- Women aged 30 and older accounted for 15 percent of all first births in 1986 compared with just 4 percent in 1970.
- Unmarried women accounted for about one in 10 first births to mothers ages 30–34 in 1986 compared with one in 20 a decade earlier.
- The educational attainment of women having their first child at ages 30 and older has increased substantially, and is higher than for women in any other age group. During the 1980s, close to one-half of the older first-time mothers have been college graduates, compared with one-fourth of comparable women in 1970.
- Greater educational attainment is associated with more timely receipt of prenatal care and a better outcome in terms of birthweight. More than 90 percent of mothers in their thirties who were college graduates began prenatal care in the first trimester. Only 5.8 percent of first births to college graduates ages 30–34 were low birthweight in 1986 compared with 7.5 percent of all first births to mothers in this age group.

Sample Size and Power Based on the Population Attributable Fraction

WARREN S. BROWNER, MD, MPH, AND THOMAS B. NEWMAN, MD, MPH

Abstract: Most methods for calculating sample size use the relative risk (RR) to indicate the strength of the association between exposure and disease. For measuring the public health importance of a possible association, the population attributable fraction (PAF)—the proportion of disease incidence in a population that is attributable to an exposure—is more appropriate. We determined sample size and power for detecting a specified PAF in both cohort and case-control studies and compared the results with those obtained using conventional estimates based on the relative risk. When an exposure is rare, a study that has little power to detect a small RR often has adequate power to detect a small PAF. On the other hand, for common exposures, even a relatively large study may have inadequate power to detect a small PAF. These comparisons emphasize the importance of selecting the most pertinent measure of association, either relative risk or population attributable fraction, when calculating power and sample size. (*Am J Public Health* 1989; 79:1289–1294.)

Introduction

In most observational studies the relative risk (RR)—the incidence rate of a disease in persons exposed to a risk factor divided by the incidence rate in persons without the exposure—measures the association between exposure and disease. The relative risk is often used to indicate the strength of that association; in general, the stronger an association, the more likely that it is causal. The goal of most observational studies is the discovery of causal relationships, and sample size and power are generally calculated to detect a given relative risk.

In other circumstances, however, an investigator may be more interested in determining the overall impact of an association than its causal strength. For example, an investigator studying congenital heart disease might want to have sufficient sample size to detect those exposures associated with 5 percent or more of the cases. For this purpose, the population attributable fraction (PAF)—the proportion of disease incidence in a population that can be attributed to a particular exposure—is a more useful measure than the relative risk. Assuming that the exposure is a cause of the disease, the population attributable fraction indicates the potential public health importance of an association. The higher the PAF, the greater the potential for reducing the incidence of the disease by modifying that exposure.[1]

The population attributable fraction[2,3] (also called attributable risk,[4] population attributable risk proportion,[5] etiologic fraction[6]) is defined as the excess incidence of a disease that is due to an exposure in a population, divided by the total incidence of the disease in the population. If I is the incidence rate of a disease in the population, and I_{un} is the incidence rate in those without the exposure, then the excess incidence of the disease due to the exposure is $I - I_{un}$, and:

$$PAF = \frac{(I - I_{un})}{I} \qquad (1)$$

For example, if the annual incidence of lung cancer in middle-aged men in the United States is 46 per 100,000, and the incidence in non-smokers is 10 per 100,000, then 78 percent of the lung cancer in this age group can be attributed to current smoking. In its more familiar form, as it was introduced 35 years ago by Levin,[7] the PAF equals:

$$\frac{p_x\,(RR - 1)}{p_x\,(RR - 1) + 1} \qquad (2),$$

where p_x is the prevalence of the exposure (risk factor). Since the RR of lung cancer in smokers is about 10, and the prevalence of smoking among middle-aged men is about 0.40,

$$PAF = \frac{.4\,(10 - 1)}{.4\,(10 - 1) + 1} = 0.78.$$

The PAF depends upon both the exposure prevalence and the relative risk: at any given population attributable fraction, rare exposures must be associated with large relative risks to have even a modest PAF. (The relationship between exposure prevalence, relative risk, and PAF is discussed further in several of the references.)[8–10] At an exposure prevalence of 5 percent, for example, the relative risk must be 6 in order to have a PAF of 20 percent. Conversely, a common exposure can be responsible for the same PAF with a small relative risk: at an exposure prevalence of 50 percent, a relative risk of only 1.5 has a PAF of 20 percent.

As we will show, at the same PAF, it turns out to be "easier" (power is greater, or sample size is smaller) for a study to detect a rare exposure with a large relative risk than to detect a more common exposure with a smaller relative risk. For example, in a case-control study with one control per case, at one-sided alpha = 0.025 and power = 0.80, at a PAF of 20 percent, 64 subjects are required when the exposure prevalence is 5 percent (and RR = 6), whereas 408 subjects are needed when the exposure prevalence is 50 percent (and RR = 1.5).

We have estimated sample size and power for observational studies based on the detection of a given population attributable fraction for a binary (yes/no) exposure, and compared them with conventional estimates based on detecting a given relative risk.[11–13] These methods complement currently available methods for determining the confidence interval for a population attributable fraction once a study has been completed.[14,15]

Methods

To estimate the sample size required to detect a specified population attributable fraction, we developed sample size

This paper, submitted to the Journal February 29, 1988, was revised and accepted for publication January 20, 1989.

formulas, using the PAF, rather than the relative risk or odds ratio, as the measure of association. The null hypothesis (H_0) is that the PAF = 0; the alternative hypothesis (H_1) is that the PAF ≥ 0. We applied the Fleiss-Tytun-Ury approximation for the continuity correction.[11]

Sample Size for Cohort Studies

Using the risk ratio (RR) as the measure of association, the number of unexposed subjects, m′, required in a cohort study, prior to applying the Fleiss-Tytun-Ury approximation for the continuity correction, is:[12]

$$m' = \frac{[Z_\alpha \sqrt{\bar{I}(1-\bar{I})} + Z_\beta \sqrt{p_x I_{un}(1-I_{un}) + (1-p_x) RR I_{un}(1-RR I_{un})}]^2}{p_x [(RR-1) I_{un}]^2}$$

(We assume that p_x, RR, I, and I_{un} in the cohort estimate their respective values in the population.)

We can replace RR with PAF by solving equation 2:

$$RR = \frac{PAF}{p_x (1 - PAF)} + 1 \qquad (3),$$

and can replace I_{un} by solving equation 1:

$$I_{un} = I (1 - PAF).$$

Note that:

$$RR - 1 = \frac{PAF}{p_x (1 - PAF)},$$

and

$$(RR-1)\, I_{un} = (1/p_x)\, I\, PAF.$$

Thus:

$$m' = \frac{p_x (Z_\alpha \sqrt{I(1-I)} + Z_\beta \sqrt{p_x T + (1-p_x) U})^2}{PAF^2 I^2}$$

where

$$T = [I (1 - PAF)] (1 - [I(1 - PAF)]),$$

and

$$U = p_x^{-2}(I[PAF + p_x(1-PAF)])[p_x - (I[PAF + p_x (1-PAF)])].$$

Applying the approximate continuity correction, the corrected number of unexposed subjects required, m, is obtained:

$$m = m' + \frac{1}{p_x (RR - 1) I_{un}},$$

$$= m' + \frac{1}{PAF\, I}.$$

Thus the total number of subjects, N, required in the cohort would be:

$$N = \frac{m}{(1 - p_x)}.$$

Sample Size for Case-Control Studies

We assume that the disease is rare, or that incidence-density sampling of controls has been used,[16] and that cases and controls represent the population with and without the disease, respectively. Then p_x, the proportion of controls with a binary exposure, is approximately equal to the proportion of the population with the exposure; p_c, the proportion of cases with an exposure, is approximately equal to the proportion of incident cases in the population with the exposure; and the odds ratio (OR) is approximately equal to the rate ratio for the disease. Let P equal the overall proportion of subjects (cases and controls) exposed, and b represent the control:case ratio.

The total number of cases, c′, required in a case-control study, prior to applying the Fleiss-Tytun-Ury approximation for the continuity correction, is:[13]

$$c' = \frac{(Z_\alpha \sqrt{(1+1/b)P(1-P)} + Z_\beta \sqrt{(p_c)(1-p_c) + p_x(1-p_x)/b})^2}{(p_c - p_x)^2}.$$

When the odds ratio (OR) serves as the measure of association:

$$p_c = \frac{p_x\, OR}{1 + p_x (OR - 1)}.$$

By analogy to equation 3:

$$OR = \frac{PAF}{p_x (1-PAF)} + 1.$$

Since by definition:

$$OR = \frac{p_c (1 - p_x)}{p_x (1 - p_c)},$$

thus

$$p_c = PAF + p_x (1 - PAF),$$

when the PAF serves as the measure of association.

With b controls per case:

$$P = \frac{p_c + b\, p_x}{b + 1}$$

$$= \frac{PAF\ (1 - p_x) + p_x\ (b + 1)}{(b + 1)}.$$

Thus:

$$c' = \frac{(Z_\alpha \sqrt{X} + Z_\beta \sqrt{Y})^2}{PAF^2 (1 - p_x)^2},$$

where

$$X = \frac{[PAF(1-p_x) + p_x(b+1)]\ (b+1-[PAF\ (1-p_x) + p_x\ (b+1)])}{b\ (b+1)},$$

and

$$Y = [PAF + p_x\ (1-PAF)]\ (1-p_x)\ (1-PAF) + [p_x\ (1-\ p_x)/b].$$

Applying the Fleiss-Tytun-Ury correction, the corrected number of cases, c, would be:

$$c = c' + \frac{b + 1}{b \mid p_c - p_x \mid}$$

$$= c' + \frac{b + 1}{b\ PAF\ (1 - p_x)}$$

Results

We compared the results of sample size and power calculations based on a specified population attributable fraction with the usual ones based on the relative risk or odds ratio for cohort and case-control studies. We used a one-tailed alpha of 0.025 (Z = 1.96).

Table 1 presents the number of subjects required in a cohort study to detect a given population attributable fraction for different combinations of the incidence of a disease and the prevalence of an exposure. If the incidence of a disease is 5 percent, for example, 59,371 subjects would be necessary to detect an exposure of prevalence 0.80 that was responsible for 10 percent of the disease (the corresponding relative risk is 1.14).

Table 2 presents the number of cases required in a case-control study to detect a given PAF for different combinations of the number of controls per case (the control: case ratio) and the prevalence of an exposure among the controls. If there are 2 controls per case, for example, 28 cases would be needed to detect an exposure of prevalence 0.30 that was responsible for 50% of the disease (an odds ratio of 4.33).

Comparison with Power and Sample Size Based on Relative Risk or Odds Ratio

Figure 1 shows the familiar relationship between power and exposure prevalence (P_x, the proportion exposed to a risk factor) at several relative risks for a reasonably large cohort study (chosen to be the same size (N = 2179) and disease incidence (I = 0.08) as the Framingham, Massachusetts study of coronary heart disease in middle-aged men[17]). Note that as the prevalence of the exposure approaches approximately 0.50, power increases. Thus the more common an exposure, up until about half of the cohort has been exposed, the greater the power to detect a given relative risk. For all but the rarest (or most common) exposures, there would be enough subjects in the cohort to have adequate power to detect relative risks of 1.8 or more.

By contrast, in Figure 2 power is plotted as a function of the exposure prevalence for several values of the population attributable fraction. Power is maximal as prevalence approaches zero (and the corresponding relative risk approaches infinity), and decreases rapidly as prevalence increases (and the corresponding relative risk gets smaller). Thus even a study with more than 150 events among more than 2000 subjects would have only limited power to detect population attributable fractions of 15 percent or less for common exposures ($P_x > 0.40$). On the other hand, the study would have sufficient power to detect uncommon exposures ($P_x < 0.10$) associated with population attributable fractions as small as 5 percent.

Figure 3 shows the familiar relationship between: 1) the number of cases required in a case-control study; 2) Px, the proportion of controls exposed to a risk factor; and 3) the odds ratio (with two controls per case, at a power of 0.80). The number of cases required to detect a given OR is minimized as P_x approaches about 0.50. For example, a

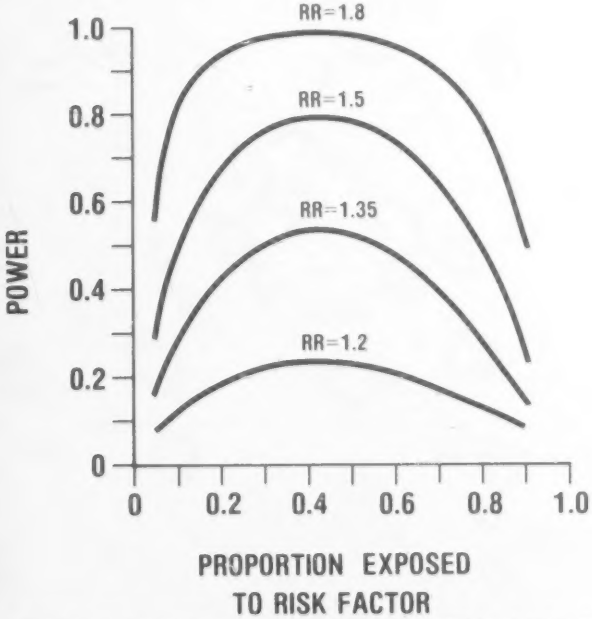

FIGURE 1—Power to detect a given relative risk (RR) for CHD as a function of the proportion of cohort exposed to a risk factor (P_x) in a cohort study (with N = 2179, incidence proportion = 0.08, and one-tailed alpha = 0.025).

*Use upper number if overall incidence of disease is 0.01 (1 per 100); middle number if incidence is 0.05; and lower number if incidence is 0.10.

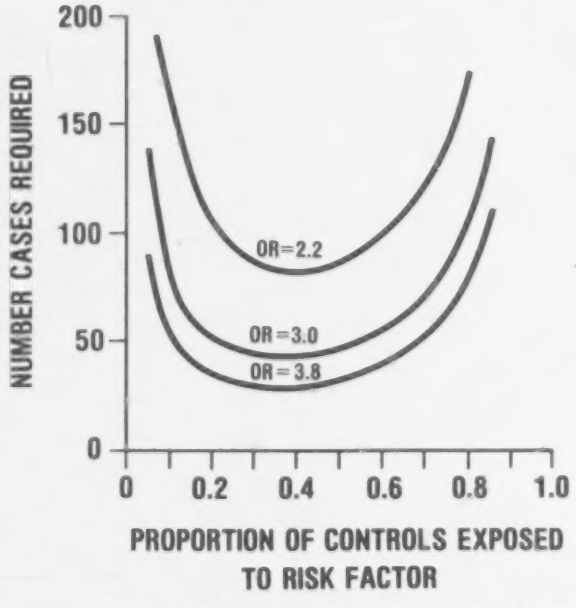

FIGURE 3—Number of cases required to detect a given odds ratio (OR) as a function of the proportion of exposed controls (P_x), at control:case ratio = 2:1, power = 0.80, one-tailed alpha = 0.025.

case-control study with 91 cases and 182 controls—the same size as a study of risk factors for hip fracture reported by Paganini-Hill, *et al*,[18]—would have a power of 0.80 to detect an odds ratio of about 2.2 for reasonably common exposures ($0.30 < P_x < 0.55$). As expected, however, if only 1 in 20 controls was exposed, the study would have adequate power to detect only odds ratios of 3.8 or more.

When plotted as function of P_x, for any given value of the population attributable fraction (Figure 4), the number of required cases is minimized as P_x approaches zero. For a rare exposure like diabetes ($P_x = 0.05$[18]), a study with about 90 cases and 180 controls, for example, would have a power of 0.80 to detect a population attributable fraction of 15 percent (a corresponding relative risk of 4.5). But for a more common exposure like use of sedative-hypnotic medications ($P_x = 0.52$[18]), the study would have adequate power to detect only population attributable fractions of more than 40 percent (relative risks of 2.3 or more).

Discussion

The relationship between power, relative risk and population attributable fraction may seem paradoxical. Even though the power to detect a given relative risk (or odds ratio) increases as an exposure becomes more common (up to about 50 percent), the power to detect a given population attributable fraction actually decreases. This occurs because the population attributable fraction depends upon both the prev-

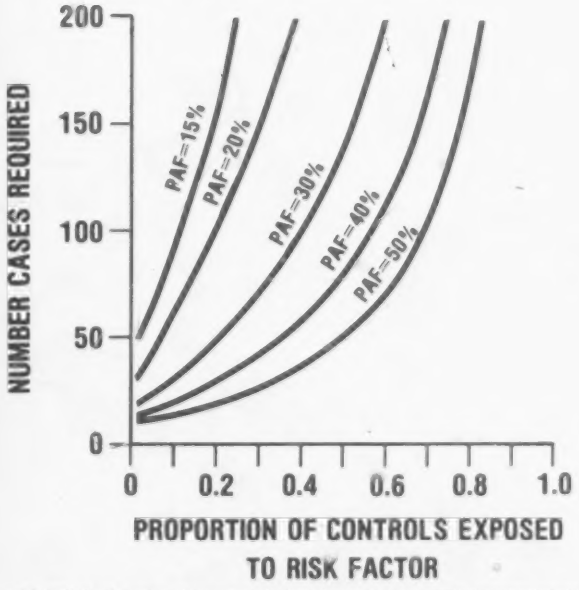

FIGURE 4—Number of cases required to detect a given population attributable fraction (PAF) as a function of the proportion of exposed controls (P_x), at control: case ratio = 2:1, power = 0.80, one-tailed alpha = 0.025.

alence of the exposure and the relative risk: for a given population attributable fraction, an increase in exposure prevalence is accompanied by a compensatory decrease in the relative risk. This decrease in the relative risk reduces power more than the increase in the prevalence raises it. The net result is a reduction in the power to detect a given population attributable fraction.

Thus only very large studies have adequate power to determine whether prevalent exposures are associated with substantial population attributable fractions. Consider a common exposure such as dietary consumption of red meat (say $P_x = 0.8$). Even a large case-control study (with 150 cases and 300 controls) would have less than 80 percent power to detect, for example, whether eating red meat accounted for 50 percent of colon cancer in the US. There are no easy solutions to this problem. Power can be somewhat increased by treating an exposure as a continuous or categorical variable if that is an option; the population attributable fraction can be determined for such exposures.[19] To maximize PAF, a continuous risk factor, such as serum cholesterol, should be dichotomized at the threshold above which disease risk appears to increase. Among the cohort of 361,662 men screened for the Multiple Risk Factor Intervention Trial, for example, dichotomizing serum cholesterol at 181 mg/dl (4.68 mmol/l), resulted in a PAF of 48 percent.[20] Alternatively, it may be necessary to compare the prevalence of

certain exposures in areas of high and low disease incidence, such as the US and Japan in the example of colon cancer,[21] to suggest potential risk factors.

By contrast, even studies with relatively few subjects often have adequate power to detect small population attributable fractions associated with a rare exposure like diabetes. Our results should be reassuring to investigators concerned about having sufficient power to detect exposures that are important from the public health point of view, but rare.

As is the case when sample size and power are based on the relative risk, these estimates assume that there are no confounders of the relationship between the exposure and the disease. Especially if the associations between exposure and confounder, and between confounder and disease, are strong, it is prudent to make separate sample size estimates at each level (stratum) of the confounder.[22,23]

Use of the relative risk as a basis for calculating sample size and power is appropriate for most observational studies. However, many such studies are also concerned with discovering exposures that are associated with a substantial population attributable fraction and have an important public health impact.[24,25] Investigators planning such studies should be aware that very large sample sizes may be required to detect meaningful population attributable fractions for common exposures, and that rare exposures associated with substantial population attributable fractions can be detected even in small studies. Calculation of sample size and power based on the population attributable fraction may be helpful to investigators interested in the potential public health impact of the associations they hope to detect.

Call for Abstracts

APHA Late-Breaker Epidemiology Exchange Session

The Epidemiology Section will again sponsor a Late-Breaker Epidemiologic Exchange at APHA's annual meeting in Chicago, Illinois. The Exchange, to be held on Wednesday, October 25, 1989, will provide a forum for presentation of epidemiologic investigations, studies, methods, etc., which have been conceived, conducted, and/or concluded so recently that abstracts could not meet the deadline for submission to other Epidemiology Sessions. Papers submitted should report on work conducted during the last 6–12 months.

Abstracts should be limited to 200 words; no special form is required. Abstracts should be submitted to Robert A. Gunn, MD, Division of Field Services, Epidemiology Program Office, Bldg. 1, Room 5127, C08, Centers for Disease Control, Atlanta, GA 30333—telephone; (404) 639-3187—and must be received by *September 15, 1989.*

Chronic Stressors and Maternal Depression: Implications for Prevention

SUEZANNE T. ORR, PHD, SHERMAN A. JAMES, PHD, BARBARA J. BURNS, PHD, AND BRUCE THOMPSON, PHD

Abstract: We report on the use of an instrument to measure exposure to stressors among 149 women presenting with their children for pediatric care at an urban primary care center. Overall, 38.3 percent of the women had significant levels of depressive symptoms; 71.4 percent of those in the "high stress" group had an adjusted prevalence odds ratio of 5.00 [95% CI = 2.12, 11.82]. We conclude that screening in the pediatric office is feasible for identifying women at high risk of becoming depressed. (*Am J Public Health* 1989; 79:1295–1296.)

Introduction

The prevalence of significant levels of depressive symptomatology is quite high among mothers of young children.[1,2] Most such women have regular and continuing contact with a pediatrician, thus placing the pediatrician in a position to detect maternal depression. In a prior study of mothers bringing children into an urban primary care center,[3] we found the overall prevalence of significant levels of depressive symptomatology to be around 35 percent. Maternal depression has been shown to be correlated with significant physical and mental health, and school/behavioral problems among school-aged children.[4–7] Thus, high levels of depressive symptomatology have implications for the well-being of children.

Many factors are associated with increased risk of depression among women, including exposure to psychosocial stressors, lower socioeconomic status, and single parenthood. Of these factors, exposure to psychosocial stressors may be of special importance.[8–11*] Exposure to stressors, unlike demographic factors, may be amenable to interventions that could reduce depressive symptoms. Ilfeld and others have demonstrated in large community-based studies that exposure to stressors is present *prior* to the onset of depression.[8,11,12] Thus, "screening" women for exposure to stressors could lead to the development of preventive interventions.

In this paper, we present data collected from women presenting with their children in a large pediatric practice who were administered a questionnaire to assess exposure to stressors, and an instrument to measure depressive symptoms.

Methods

Data were collected during April–May 1984 at an urban pediatric primary care practice based at Sinai Hospital in Northwest Baltimore city. Mothers of children ages 5–10 were eligible for inclusion if they presented with a child for any type of pediatric care during the study period. The age restriction was imposed because one study instrument was designed for use as part of a larger research effort to identify and reduce risks for school and behavioral problems. The refusal rate was less than 5 percent.

Exposure to stressors was assessed using the Social Environment Inventory (SEI), a self-report instrument which measures exposure to acute (i.e., life events) and chronic stressors (e.g., financial, marital, employment, housing problems).[13]

Depressive symptomatology was measured using the Center for Epidemiologic Studies Depression Scale (CES-D).[14] Contingency tables were constructed to evaluate potential associations between the independent variables and CES-D category (0-15, 16 or above), and prevalence odds ratios were calculated as a measure of the strength of associations.[15] A multiple logistic regression analysis was performed in order to evaluate the associations between each independent variable and depression (as a dichotomy), controlling for the effects of all of the other independent variables. The beta coefficients and standard errors from the logistic model were used to calculate adjusted odds ratios and 95 percent confidence intervals.

Results

During the study period, 149 women were administered the study instruments. As shown in Table 1, approximately 56 percent of the women were single parents; 84 percent were Black; 20 percent had less than a high school education.

Overall, 38.3 percent of the sample scored in the depressed range (16 or greater) on the CES-D, similar to the proportion depressed in our previous report.[3] As shown in Table 1, exposure to stressors was significantly associated with risk for depressive symptomatology. The prevalence of depression among mothers scoring in the upper third of scores on the SEI was about three times that of women scoring in the lowest or middle thirds of scores on the SEI, and the adjusted prevalence odds ratio was 5.00 (95% CI = 2.12, 11.82). Terms to represent exposure-confounder interactions were not included in the model, since there appeared to be homogeneity of effects across strata of the confounders.

Discussion

These data suggest a rather high prevalence of depressive symptomatology, especially among mothers exposed to high

levels of psychosocial stressors, the strongest predictor of depressive symptoms in the multiple logistic regression model.

An obvious limitation of these data is their cross-sectional nature. Women who have high levels of depressive symptomatology may systematically inflate self-reports of exposure to psychosocial stressors, or depression may lead to problems with family and children. Alternatively, there are sound empirical reasons to believe that the occurrence of life stress precedes the onset of depressive symptomatology.[8,11,12]

A woman who scores 10 or more on the stressor measure can be considered to be at high risk of being depressed. Most of the measured stressors are of a chronic nature, rather than transient events. It may be possible to develop primary preventive interventions that reduce exposure to some stressors or, alternately, enhance the skills or resources of the women to cope with psychosocial stressors. In this connection, prior research has shown that as the number of stressors to which a woman was exposed increased, so did the risk of depression.[8] One might infer then that reducing the number of stressors to which a woman was exposed could lead to a reduction in risk of depression. Such interventions might include referrals for assistance with child care, or housing, or other such programs. Working to improve the social conditions of mothers and children may be an effective means to reduce their exposure and/or vulnerability to socioenvironmental stressors and associated higher risks of maternal depression. This, in turn, may lead to decreased risk of physical and mental illness and school problems among children.

APPENDIX

The Social Environment Inventory (SEI)

The SEI is a self-report instrument which measures exposure to acute (i.e., life events) and chronic stressors (e.g., financial, marital, employment, housing problems) (It also has items to measure access to social support, but these were not included in the present analysis). The instrument was designed to be administered in the pediatric primary care setting to women with school age children, ages 5–10. It has been tested for both reliability and validity. The reliability assessment focused on reproduceability of scores over a 30-day period. Spearman's rank order correlation coefficient over the 30-day time period for exposure to stressors was .74. The validity assessment focused on construct validity. A measure of construct validity was depression, since exposure to stressors among women is known to be associated with depression. It was found that high levels of exposure to stressors as measured by the SEI was significantly associated with an increased risk of depression (prevalence ratio = 3.7, $p < .001$). Additional analyses were conducted to determine if SEI stressor scores were associated with race or maternal education. Neither of these factors was significantly associated (using the chi square statistic for analysis) with SEI scores, suggesting that something other than those sociodemographic variables examined explained variation in scores.

The number of affirmative responses (i.e., experiencing a stressor) on the SEI are summed into a total "stress" score. In keeping with earlier analyses, scores were divided into approximately equal tertiles. For this analysis, the women with scores in the upper third (score of >10) were compared with those in the lower two-thirds.

Immunity to Diphtheria and Tetanus in Inner-City Women of Childbearing Age

BERYL A. KOBLIN, PHD, AND TIMOTHY R. TOWNSEND, MD

Abstract: This study was conducted to determine immunity to diphtheria and tetanus in 232 inner-city women experiencing a recent birth. Forty-three (18.5 percent) of the women had levels of diphtheria antitoxin below the protective level (<0.01 unit/ml), whereas only 10 (4.3 percent) had insufficient levels of tetanus antitoxin. The percent of women susceptible increased with age, with 33 percent and 25 percent of women over the age of 30 years susceptible to diphtheria and tetanus, respectively. (*Am J Public Health* 1989; 79:1297–1298.)

Introduction

Tetanus and diphtheria are uncommon diseases in the United States.[1] However, both are associated with high morbidity and mortality and are preventable by immunization. For infants and children, immunization against diphtheria and tetanus is routine and mandatory for entrance into grade school. Surveys based on household interviews indicate that 95 percent of children entering grade school receive three or more doses of diphtheria-tetanus-pertussis (DTP) vaccine.[2]

Adults who have completed a primary series of tetanus and diphtheria toxoids are recommended to receive a booster every 10 years.[3] However, from 1977–82, 56 percent of diphtheria cases and 89 percent of tetanus cases occurred in adults indicating that many adults have insufficient levels of antitoxin.[3] Serosurveys in adults have indicated that tetanus and diphtheria antitoxin levels were deficient in 20 percent to 80 percent,[4] with percentages higher for women than men, especially in the middle-aged and elderly populations.[4–6]

Few recent immune status data are available on women of childbearing age from low socioeconomic areas. During a study of the immune response of preterm and fullterm infants to DTP vaccine[7] approved by the Joint Committee on Clinical Investigation of the Johns Hopkins Medical Institutions, we obtained samples from women whose infants attended one of two inner-city pediatric clinics. As a part of this study, the authors determined the immunity to diphtheria and tetanus in this group of women experiencing a recent birth.

Methods

Sera were collected between August 1984 and June 1986 from women whose infants attended one of two outpatient pediatric clinics serving mainly a Medicaid population at the Johns Hopkins Hospital.[7] The mothers of all preterm infants born during the study period and mothers of fullterm infants chosen randomly on the following clinic day were approached for participation. If the mother chosen was not present in the clinic or refused to participate, then another mother was chosen at random from the appointment list. Informed consent was obtained and a specimen of blood collected by venipuncture. Each women was interviewed and information collected on age, race, and education.

Levels of diphtheria and tetanus antitoxin were determined by the indirect hemagglutination assay adapted to microtiter technique.[8] To allow comparisons with previous studies, an antitoxin level of ≥0.01 unit/ml was considered protective.

The relation between age and percent of women susceptible was analyzed using the Chi-square test for trend.[9]

Results

One hundred fifty-seven mothers of preterm infants and 273 mothers of fullterm infants were eligible for the study; samples from 99 (63.1%) mothers of preterm infants and 133 (48.7%) mothers of fullterm infants were examined.

The study population consisted of 232 women aged 13 to 46 years (mean = 23 years). Thirty-two percent of the women were under the age of 20. Nearly all of the women were Black (95%); 117 (50%) had completed at least a high school education.

Forty-three (18.5%) of the women had levels of diphtheria antitoxin below the protective level (Table 1). There was an increasing percentage of women susceptible to diphtheria with increasing age. There were no differences in the percentage of women unprotected by level of education.

Ten (4.3%) of the women had levels of tetanus antitoxin less than 0.01 unit/ml, thus considered unprotected (Table 1). The percent of women with titers below the protective level, again, increased with age, with none of the women under the age of 20 unprotected compared to 25 percent of those over the age of 30 years. Again, there were no differences in the percent of women unprotected by level of education.

In every age group, the percent of women susceptible was greater for diphtheria than for tetanus.

Discussion

Surveys conducted in other populations of women over

TABLE 1—Number and Percent of Childbearing Women Susceptible* to Diphtheria and Tetanus by Age

Age (years)	N	Diphtheria* N (%)	Tetanus* N (%)
<16	25	2 (8.0)	0 (0.0)
17–19	49	6 (12.2)	0 (0.0)
20–22	64	12 (18.8)	1 (1.6)
23–25	36	5 (13.9)	0 (0.0)
26–30	34	10 (29.4)	3 (8.8)
>30	24	8 (33.3)	9 (25.0)
Total	232	43 (18.5)	10 (4.3)

*Susceptible = <0.01 unit/ml of antitoxin.
χ^2 test for trend for diphtheria = 7.88; p = 0.005
χ^2 test for trend for tetanus = 20.18; p < 0.0001

the last 20 years have found a higher percent of women susceptible compared to the present study.[4,5,10] However, these studies have also reported an increase in the proportion susceptible with age. Millian, *et al*,[4] found low levels of tetanus antitoxin (<0.01 unit/ml) in 25 percent of women aged 20–29 years and 37 percent of women aged 30–39 years. Levels of diphtheria antitoxin <0.02 unit/ml were found in 15 percent of women aged 15–19 years, 19 percent of women 20–29 years, and 24 percent of women 30–39 years.[4]

The participants in this study were a group of self-selected women whose infants attended outpatient clinics that serve mainly a Medicaid population in a large city. However, they were a high-risk population for low utilization of medical care and discontinuity of care. Additional data on immunization history would have helped to further characterize this population.

In the present study, the percent of women susceptible to diphtheria was higher in all age groups compared to tetanus. One reason for this observation may be the use of tetanus toxoid alone as the practice for wound prophylaxis after trauma instead of the combined diphtheria-tetanus toxoids. Another reason is that diphtheria toxoid is less antigenic than tetanus toxoid and therefore the duration of seroprotection following immunization may be less than that observed for tetanus toxoid.[5]

The level of 0.01 unit/ml was chosen as the indicator for protection in this study to enable comparisons to other studies. However, the protective level of antitoxin for diphtheria is less well defined than that for tetanus.[11,12] Outbreaks do occur in communities in which immunization has been extensive and immunization with diphtheria toxoid may modify disease rather than prevent its occurrence.[13]

Susceptibility to diphtheria in the older age groups can be a result of lack of exposure to diphtheria in the past, lack of completion of the primary series in childhood, or lack of boosters since childhood. Since immunity to tetanus is entirely dependent on immunization, the women in the older age groups did not complete their primary series, or did not receive recent boosters. In Maryland, the requirement for immunization before entry into schools became effective in 1973 for children in nursery school through sixth grade.[14] Therefore, the women born after 1962, those under age 23 at the midpoint of the study, would have been the most likely to have been immunized in this program.

Two major areas of concern arise from these data:

- As these women age, they will contribute to the already susceptible elderly population. Second, the protection of infants against diphtheria and tetanus in their first few months of life is dependent on the mother passing adequate levels of antitoxin to the fetus during pregnancy. Given that diphtheria and tetanus antibodies readily cross the placenta during pregnancy,[15,16] regular boosters of women would help to protect their newborn infants in the first few months of life.
- All of the women in this study had been hospitalized for delivery a few months before blood drawing. The immediate post delivery to preuischarge from the hospital period could have been an opportunity to provide vaccines and toxoids recommended for adult immunization. An alternative opportunity for immunization is during visits to antenatal or pediatric clinics.

ACKNOWLEDGMENTS

We are indebted to the staff of the Johns Hopkins Hospital Pediatric outpatient clinics; to Lynn Nauman and Robin Gay for their clinical assistance; to the Maryland State Department of Health and Mental Hygiene for laboratory testing; and especially to the women who participated in this study. This research was presented at the 116th annual meeting of the American Public Health Association in Boston, Massachusetts, November 1988.

This research was supported by a grant from the Maryland State Department of Health and Mental Hygiene.

Caffeinated Beverages and Low Birthweight: A Case-Control Study

BETTE J. CAAN, DRPH, AND MARILYN K. GOLDHABER, MPH

Abstract: A case-control study, examining the effect of first trimester maternal caffeine consumption on low birthweight, was performed in the Kaiser Permanente Medical Care Program. Heavy consumption (>3 servings/day) of coffee, cola and >300 mg/day of caffeine from all sources (coffee, tea and cola) was associated with a marginally increased risk of low birthweight. Our data support previous findings of a modest effect of caffeine consumption on fetal growth. (*Am J Public Health* 1989; 79:1299–1300.)

Introduction

Several relatively small studies performed prior to a 1981 Federal Drug Administration warning which advised women to limit their caffeine intake[1] showed a positive relationship between caffeine consumption and low birth-weight (LBW) or prematurity.[2–4] Since the 1981 warning, three major studies have been reported: a retrospective study of 12,205 prenatal patients in Massachusetts showing no relation between caffeine and LBW adjusted for cigarette smoking,[5] a retrospective survey in 9,921 Japanese women demonstrating a relation between high levels of caffeine consumption and small fetal size for gestational age,[6] and a prospective study of 3,891 antenatal patients in Connecticut showing a twofold risk of LBW associated with moderate caffeine consumption and a fourfold risk of LBW associated with heavy caffeine consumption.[7]

Methods

From a large case-control study of aerial malathion spraying and adverse pregnancy outcomes, we identified a cohort of women who had been pregnant during the period of malathion spraying in Northern California (July 1, 1981–June 30, 1982) and who had sought care at the Kaiser Permanente facility located in the sprayed county, or in either of two Kaiser Permanente facilities in demographically comparable areas outside the spray area. We retrospectively followed 9,564 pregnancies, an estimated 95 percent of the pregnancies that occurred during that time period at those facilities. Details of the methods are reported elsewhere.[8] One hundred percent of women in the larger case-control study with adverse outcomes and 20 percent of women with normal live births were selected for a post-pregnancy interview. Of those women, 85 percent completed the post-pregnancy interview, which elicited average daily consumption of caffeinated coffee, tea, and soft drinks during the first trimester.

Ninety-seven women were identified among the respondents as having infants with intrauterine growth retardation, defined as two standard deviations or more below the mean weight for gestational age.[9] An additional 34 women with live born babies weighing 2500 grams or less, but without growth retardation, were included as cases. No difference in caffeine consumption was found between these two groups, and they are combined in this paper. All 131 women are referred to as LBW. One hundred thirty-six controls were randomly selected from the remainder of normal pregnancies that resulted in live births.

Five caffeine measures were used: caffeine from all beverages, caffeine from coffee, caffeine from coffee and colas combined, number of servings of tea, and number of servings of colas. For each of these measures, women were divided into three categories based on their daily intake of caffeine: none, light-to-moderate (<300 mg or <3 servings) and heavy (>=300 mg or >=3 servings). We estimated the relative risk of LBW for the light-to-moderate and heavy consumers, each compared to the nonusers, with odds ratios (OR)[10] unadjusted and adjusted for ethnicity, alcohol intake, cigarette use, prepregnancy weight, weight gain, and parity.

Results

Several demographic and behavioral characteristics of cases and controls are summarized in Table 1. Among the cases, there were more Blacks and Asians and fewer Whites and Hispanics. Cases had a significantly lower prepregnancy weight, a significantly higher consumption of cigarettes and lower weight gain during pregnancy. In both groups, cola drinks were the most frequently consumed beverage. Heavy consumption of coffee was greater than heavy consumption of either cola or tea in both the cases and controls. Only 8.1 percent of the controls and 13.8 percent of the cases drank greater than 300 mg of caffeine daily.

No increased risk was seen with light-to-moderate consumption, with the crude or adjusted OR, but there was a suggestion of increased risk with heavy consumption of coffee, of cola, and of total caffeine (Table 2).

Discussion

We found a tripled risk of delivering a LBW infant with levels of caffeine consumption greater than 300 mg/day (OR = 2.94), but the estimate was necessarily imprecise because of the small study size (95% CI = .89, 9.65). A larger study would have permitted greater precision, but the number of controls selected was restricted by cost. Only one other study demonstrated an increased risk of LBW at such low caffeine levels, with an OR of 2.5 at daily caffeine intakes between 151–300 mg.[7] In the majority of other studies demonstrating significant associations between caffeine and birth weight, positive associations were found only at much higher levels of caffeine consumption (>500 mg/day).[3,4,6]

These findings would be distorted by recall bias if women who had pregnancies with adverse outcomes selectively overestimated their caffeine consumption. This bias appears unlikely since we found no relationship between spontaneous abortion, the primary outcome of interest in the larger study, and caffeine intake.

Since fetal growth is most rapid during the third trimester of pregnancy, one might speculate that caffeine's effect on fetal growth would be most marked during that period. We made the following assumptions about caffeine intake in the

Weight gain during pregnancy (lbs)	28.13	1.24	35.14	1.19

third trimester in order to explain the biological plausibility of our hypotheses. Heavy consumers during the first trimester were likely to continue heavy consumption throughout their pregnancy, while nonconsumers either continued their same pattern of nonconsumption or increased to light-to-moderate consumption in later trimesters.

The evidence from this study, in combination with evidence from several other studies carried out over the last decade, suggests that caffeine, as found in some caffeine-containing beverages, has a small but measurable effect on fetal growth.

TABLE 2—Crude and Adjusted* Odds Ratio of Low Birthweight Associated with Exposure to Caffeinated Beverages

Caffeine Exposure	Crude Odds Ratio	Adjusted* Odds Ratio and 95% C.I.
All sources (coffee, tea + cola drinks) (mg)		
Light-moderate vs none	.96	.90 (.42–1.92)
Heavy vs none	1.76	2.94 (.89–9.65)
Coffee (no. of servings)		
Light-moderate vs none	1.02	1.02 (.53–1.95)
Heavy vs none	2.07	2.79 (.89–8.69)
Cola drinks (no. of servings)		
Light-moderate vs none	1.20	1.31 (.71–2.43)
Heavy vs none	4.13	5.87 (.72–47.83)
Tea (no. of servings)		
Light-moderate vs none	.54	.57 (.28–1.17)
Heavy vs none	1.21	1.50 (.37–6.13)
Coffee + cola drinks (mg)		
Light-moderate vs none	1.17	1.34 (.68–2.64)
Heavy vs none	2.30	3.53 (1.05–11.81)

*Adjusted for ethnicity (Black, White, Hispanic, Asian, other), alcohol intake (no. of drinks/day), cigarette use (<10 cigarettes/day, ≥10 cigarettes/day), prepregnancy weight (lbs), weight gain (lbs), parity (1, >1).

ACKNOWLEDGMENTS

The authors wish to thank Diana B. Petitti, MD, for her contribution in the development of the larger study and Bill Frank for his assistance with the medical chart reviews. This study was presented at the 116th annual meeting of the American Public Health Association in Boston, November 13–17, 1988.

Funding for this project was provided by the California Department of Health Services. Any analysis, interpretation or conclusion based on these data is that of the authors and not that of the California Department of Health Services.
